Pseudoporphyria is a cutaneous phototoxic disorder that can resemble either porphyria cutanea tarda in adults or erythropoietic protoporphyria in children (see Chap. 132). Pseudoporphyria of the porphyria cutanea tarda variety is characterized by skin fragility, blister formation, and scarring in photodistribution; it occurs in the presence of normal porphyrin levels. The other clinical pattern mimics erythropoietic protoporphyria and manifests as cutaneous burning, erythema, vesiculation, angular chickenpox-like scars, and waxy thickening of the skin. The eruption may begin within 1 day of initiation of therapy or may be delayed for as long as 1 year. The course

▲ **FIGURE 40-4** Acute generalized exanthematous pustulosis in a 48-year-old man who developed non-follicular pustules and fever after 7 days of treatment with diltiazem.

is prolonged in some patients, but most reports describe symptoms that disappear several weeks to several months after the offending agent is withdrawn. Because of the risk of permanent facial scarring, the implicated drug should be discontinued if skin fragility, blistering, or scarring occurs.[31] In addition, the use of broad-spectrum sunscreen and protective clothing should be recommended.

Both idiopathic and drug-induced linear IgA disease (see Chap. 56) are heterogeneous in clinical presentation. Cases of the drug-induced type have morphologies resembling erythema multiforme, bullous pemphigoid, and dermatitis herpetiformis. The drug-induced disease may differ from the idiopathic entity in that mucosal or conjunctival lesions are less common, spontaneous remission occurs once the offending agent is withdrawn, and immune deposits disappear from the skin once the lesions resolve.

Biopsy specimens are necessary for diagnosis. Histologically, the two entities are similar. A study suggests that, as in the idiopathic variety, the target antigen is not unique in the drug-induced disease. Although 13 percent to 30 percent of patients with sporadic linear IgA have circulating basement membrane zone antibodies, these antibodies have not been reported in drug-induced cases.[32] In patients with linear IgA bullous disease proven by direct immunofluorescence, the index of suspicion of drug induction should be higher in cases with only IgA and no IgG in the basement membrane zone.

Pemphigus may be considered as drug induced or drug triggered (i.e., a la-

TABLE 40-2
Drug Eruptions Mimicry

Clinical Presentation	Pattern and Distribution of Skin Lesions	Mucous Membrane Involvement	Implicated Drugs	Treatment
Stevens-Johnson syndrome	Atypical targets, widespread	Present	Aromatic anticonvulsants,[a] lamotrigine, sulfonamide antibiotics, allopurinol, piroxicam, dapsone	IVIg, cyclosporine, supportive care
Toxic epidermal necrolysis	Epidermal necrosis with skin detachment	Present	As above	IVIg, cyclosporine, supportive care
Pseudoporphyria	Skin fragility, blister formation in photodistribution	Absent	Tetracycline, furosemide, naproxen	Supportive care
Linear IgA disease	Bullous dermatosis	Present/absent	Vancomycin, lithium, diclofenac, piroxicam, amiodarone	Supportive care
Pemphigus	Flaccid bullae, chest	Present/absent	Penicillamine, captopril, piroxicam, penicillin, rifampin, propranolol	Supportive care
Bullous pemphigoid	Tense bullae, widespread	Present/absent	Furosemide, penicillamine, penicillins, sulfasalazine, captopril	Supportive care

IVIg = intravenous immunoglobulin.
[a]Aromatic anticonvulsants = phenytoin, carbamazepine, phenobarbital, oxcarbazepine, primidone.

tent disease that is unmasked by the drug exposure; see Chap. 52). Drug-induced pemphigus caused by penicillamine and other thiol drugs tends to remit spontaneously in 35 percent to 50 percent of cases, presents as pemphigus foliaceus, has an average interval to onset of 1 year, and is associated with the presence of anti-nuclear antibodies in 25 percent of patients.

Most patients with nonthiol drug-induced pemphigus manifest clinical, histologic, immunologic, and evolutionary aspects similar to those of idiopathic pemphigus vulgaris with mucosal involvement and show a 15 percent rate of spontaneous recovery after drug withdrawal. Treatment of drug-induced pemphigus begins with drug cessation. Systemic glucocorticoids are often required until all symptoms of active disease disappear. Vigilant follow-up is required after remission to monitor the patient and the serum for autoantibodies to detect an early relapse.[33]

Drug-induced bullous pemphigoid (see Chap. 54) can encompass a wide variety of presentations, ranging from the classic features of large, tense bullae arising from an erythematous, urticarial base with moderate involvement of the oral cavity, through mild forms with few bullous lesions, to scarring plaques and nodules with bullae.[33] In contrast to patients with the idiopathic form, patients with drug-induced bullous pemphigoid are generally younger. In addition, the histopathologic findings are of a perivascular infiltration of lymphocytes with few eosinophils and neutrophils, intraepidermal vesicles with foci of necrotic keratinocytes, thrombi in dermal vessels, and a possible lack of tissue-bound and circulating antibasal membrane zone IgG.

In the acute, self-limited condition, resolution occurs after the withdrawal of the culprit agent, with or without glucocorticoid therapy. In some patients, however, the drug may actually trigger the idiopathic form of the disease.

Erythema multiforme major, SJS, and TEN represent variants of the same disease process. Differentiation between the two patterns depends on the nature of the skin lesions and the extent of body surface area involvement[34,35] (see Chaps. 38 and 39).

The pathogenesis of severe cutaneous ADRs is unknown, although a metabolic basis has been hypothesized.[36] In addition, the detection of drug-specific T-cell proliferation provides evidence that T cells are involved in severe skin rashes.[37]

Treatment of erythema multiforme, SJS, and TEN includes discontinuance of the suspected drug(s) and supportive measures such as careful wound care, hydration, and nutritional support. The use of corticosteroids in the treatment of SJS and TEN is controversial.[38,39] Intravenous immunoglobulin (IVIg, 0.4 to 1.0 g/kg/day for 2 to 4 days) has been shown in most reports to halt progression of TEN, especially when IVIg is started early.[40,41] However, some studies have not found an improved outcome in patients with TEN who are treated with IVIg.[42] Patients who have developed a severe cutaneous ADR should not be rechallenged with the drug or undergo desensitization therapy with the medication.

Fixed Drug Eruptions

FDEs usually appear as solitary, erythematous, bright red or dusky red macules that may evolve into an edematous plaque; bullous-type lesions may be present. FDEs are most commonly found on the genitalia and in the perianal area, although they can occur anywhere on the skin surface (Fig. 40-5). Some patients may complain of burning or stinging, and others may have fever,

▲ **FIGURE 40-5** Fixed drug eruption: Tetracycline. A well-defined plaque on the knee, merging with three satellite lesions. The large plaque exhibits epidermal wrinkling, a sign of incipient blister formation. This was the second such episode after ingestion of a tetracycline. No other lesions were present.

malaise, and abdominal symptoms. FDE can develop from 30 minutes to 8 to 16 hours after ingestion of the medication. After the initial acute phase lasting days to weeks, residual grayish or slate-colored hyperpigmentation develops. On rechallenge, not only do the lesions recur in the same location, but also new lesions often appear.

More than 100 drugs have been implicated in causing FDEs, including ibuprofen, sulfonamides, naproxen, and tetracyclines. A haplotype linkage in trimethoprim-sulfamethoxazole–induced FDE has been documented.[43]

A challenge or provocation test with the suspected drug may be useful in establishing the diagnosis. Patch testing at the site of a previous lesion yields a positive response in up to 43 percent of patients. Results of prick and intradermal skin tests may be positive in 24 percent and 67 percent of patients, respectively.[45]

Anticoagulant-Induced Skin Necrosis

Anticoagulant-induced skin necrosis begins 3 to 5 days after initiation of treatment. Both coumarin and heparin (unfractionated and low molecular weight) can induce skin necrosis (Fig. 40-6). Early red, painful plaques develop in adipose-rich sites such as breasts, buttocks, and hips. These plaques may blister, ulcerate, or develop into necrotic areas. It is estimated that 1 in 10,000 persons who receive the drug is at risk of this adverse event.[46] The incidence is four times higher in women, especially in obese women, with a peak incidence in the sixth and seventh decades of life. Affected patients often have been given a large initial loading dose of coumarin in the absence of concomitant heparin therapy. An accompanying infection such as pneumonia, viral infection, or erysipelas may be seen in up to 25 percent of patients. An association with protein C and protein S deficiencies exists, but pre-treatment screening is not warranted. An association with heterozygosity for the factor V Leiden mutation has been reported.[47]

▲ **FIGURE 40-6** Skin necrosis in a patient after 4 days of warfarin therapy.

Treatment involves the discontinuation of coumarin, administration of vitamin K, and infusion of heparin at therapeutic dosages. Fresh frozen plasma and purified protein C concentrates have been used.[48] Supportive measures for the skin are a mainstay of therapy. The morbidity rate is high; 60 percent of affected individuals require plastic surgery for remediation of full-thickness skin necrosis by skin grafting. These patients may be treated with coumarin in the future, but small dosages (2 to 5 mg daily) are recommended, with initial treatment under heparin coverage.

The pathogenesis of this adverse event is the paradoxical development of occlusive thrombi in cutaneous and subcutaneous venules due to a transient hypercoagulable state. This results from the suppression of the natural anticoagulant protein C at a greater rate than the suppression of natural procoagulant factors.

Drug-Induced Lichenoid Eruptions

Drug-induced lichen planus produces lesions that are clinically and histologically indistinguishable from those of idiopathic lichen planus (see Chap. 26); however, lichenoid drug eruptions often appear initially as eczematous with a purple hue and involve large areas of the trunk. Usually the mucous membranes and nails are not involved. Histologically, focal parakeratosis, focal interruption of the granular layer, cytoid bodies in the cornified and granular layers, the presence of eosinophils and plasma cells in the inflammatory infiltrate, and an infiltrate around the deep vessels favor a diagnosis of lichenoid drug eruption.[49] Many drugs, including β blockers, penicillamine, and angiotensin-converting enzyme (ACE) inhibitors, especially captopril, reportedly produce this reaction. The mean latent period is between 2 months and 3 years for penicillamine, approximately 1 year for β-adrenergic blocking agents, and 3 to 6 months for ACE inhibitors. The latent period may be shortened if the patient has been previously exposed to the drug.[49] Resolution usually occurs with 2 to 4 months. Rechallenge with the culprit drug has been attempted in a few patients, with reactivation of symptoms within 4 to 15 days.[50]

Drug-Induced Cutaneous Pseudolymphoma

Pseudolymphoma is a process that simulates lymphoma but has a benign behavior and does not meet the criteria for malignant lymphoma. Drugs are a well-known cause of cutaneous pseudolymphomas (see Chap. 147), but the condition may also be induced by foreign agents such as insect bites, infections (e.g., HIV), and idiopathic causes.[51]

Anticonvulsant-induced pseudolymphoma generally occurs after 1 week to 2 years of exposure to the drug. Within 7 to 14 days of drug discontinuation, the symptoms usually resolve. The eruption often manifests as single lesions but can also be widespread erythematous papules, plaques, or nodules. Most patients also have fever, marked lymphadenopathy and hepatosplenomegaly, and eosinophilia.[52] Mycosis fungoides–like lesions are also associated with these drugs.[53]

Drug-Induced Vasculitis

Drug-induced vasculitis represents approximately 10 percent of the acute cutaneous vasculitides and usually involves small vessels[54] (see Chap. 164). Drugs that are associated with vasculitis include propylthiouracil, hydralazine, granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, allopurinol, cefaclor, minocycline, penicillamine, phenytoin, and isotretinoin.[55] The average interval from initiation of drug therapy to onset of drug-induced vasculitis is 7 to 21 days.[56]

The clinical hallmark of cutaneous vasculitis is palpable purpura, classically found on the lower extremities. Urticaria can be a manifestation of small vessel vasculitis, with individual lesions remaining fixed in the same location for more than 1 day. Other features include hemorrhagic bullae, ulcers, nodules, Raynaud disease, and digital necrosis.[57] The same vasculitic process may also affect internal organs such as the liver, kidney, gut, and central nervous system and can be potentially life threatening.

Drug-induced vasculitis can be difficult to diagnose and is often a diagnosis of exclusion. In some cases, serologic testing has revealed the presence of perinuclear-staining antineutrophil cytoplasmic autoantibodies against myeloperoxidase.[58] Alternative causes for cutaneous vasculitis such as infection or autoimmune disease must be eliminated. Tissue eosinophilia may be an indicator of drug induction in cutaneous

small vessel vasculitis.[59] Treatment consists of drug withdrawal. Systemic glucocorticoids may be of benefit.

Drug-Induced Lupus (See Chap. 156)

Drug-induced lupus is characterized by frequent musculoskeletal complaints, fever, weight loss, pleuropulmonary involvement in more than half of patients, and in rare cases renal, neurologic, or vasculitic involvement[60] (see Table 40-1). Most patients have no cutaneous findings of lupus erythematosus. The most common serologic abnormality is positivity for anti-nuclear antibodies with a homogenous pattern. Although antihistone antibodies are seen in up to 95 percent of drug-induced lupus, they are not specific for the syndrome and are found in 50 percent to 80 percent of patients with idiopathic lupus erythematosus. Unlike in idiopathic lupus erythematosus, antibodies against double-stranded DNA are typically absent, whereas anti–single-stranded DNA antibodies are often present.[61] Genetic factors may also play a role in the development of drug-induced lupus. HLA-DR4 is present in 73 percent of the patients with hydralazine-induced lupus and in 70 percent of patients with minocycline-induced lupus.[62] Evidence now suggests that abnormalities during T-cell selection in the thymus initiate lupus-like autoantibody induction.[63]

The identification of minocycline as a cause of drug-induced lupus makes it important for dermatologists to recognize this syndrome. Minocycline-induced lupus typically occurs after 2 years of therapy. The patient presents with a symmetric polyarthritis. Hepatitis is often detected on laboratory evaluation.[64] Cutaneous findings include livedo reticularis, painful nodules on the legs, and nondescript eruptions. Antihistone antibodies are seldom present. A study of HLA class II alleles revealed the presence of HLA-DR4 or HLA-DR2 in many of the patients.[62]

In contrast, drug-induced subacute cutaneous lupus erythematosus is characterized by a papulosquamous or annular cutaneous lesion, which is often photosensitive, and absent or mild systemic involvement. Circulating anti-Ro (Sjögren syndrome A) antibodies have also been identified in many patients. The most commonly reported causative agents are thiazide diuretics, calcium channel blockers, and ACE inhibitors. The number of patients who develop subacute cutaneous lupus erythematosus during treatment with these medications is very small, and these drugs are thought to have a low risk for causing or exacerbating cutaneous lupus.[65]

DIAGNOSIS AND MANAGEMENT

The iatrogenic disorders described here are distinct disease entities, although they may closely mimic many infective or idiopathic diseases. A drug cause should be considered in the differential diagnosis of a wide spectrum of dermatologic diseases, particularly when the presentation or course is atypical.

The diagnosis of a cutaneous drug eruption involves the precise characterization of reaction type. A wide variety of cutaneous drug-associated eruptions may also warn of associated internal toxicity (Table 40-3). Even the most minor cutaneous eruption should trigger a clinical review of systems, because the severity of systemic involvement does not necessarily mirror that of the skin manifestations.[66] Hepatic, renal, joint, respiratory, hematologic, and neurologic changes should be sought, and any systemic symptoms or signs investigated. Fever, malaise, pharyngitis, and other systemic symptoms or signs should be investigated. A usual screen would include a full blood count, liver and renal function tests, and a urine analysis.

Skin biopsy should be considered for all patients with potentially severe reactions, such as those with systemic symptoms, erythroderma, blistering, skin tenderness, purpura, or pustulation, as well as in cases in which the diagnosis is uncertain. Some cutaneous reactions, such as FDE, are virtually always due to drug therapy, and nearly 90 percent of TEN cases are also drug related.[35] Other more common eruptions, including exanthematous or urticarial eruptions, have many nondrug causes.

There is no gold standard investigation for confirmation of a drug cause. Instead, diagnosis and assessment of cause involve analysis of a constellation of features such as timing of drug exposure and reaction onset, course of reaction with drug withdrawal or continuation, timing and nature of a recurrent eruption on rechallenge, a history of a similar response to a cross-reacting medication, and previous reports of similar reactions to the same medication. Investigations to exclude nondrug causes are similarly helpful.

Several in vitro investigations can help to confirm causation in individual cases, but their exact sensitivity and specificity remain unclear. Investigations include the lymphocyte toxicity and lymphocyte transformation assays.[11,12] Penicillin skin testing with major and minor determinants is useful for confirmation of an IgE-mediated immediate hypersensitivity reaction to penicillin.[67] Patch testing has been used in patients with ampicillin-induced exanthematous eruptions[68] and in the ancillary diagnosis of FDEs. Patch testing has greater sensitivity if performed over a previously involved area of skin.[69]

Cutaneous drug eruptions do not usually vary in severity with dose. Less severe reactions may abate with continued drug therapy (e.g., transient exanthematous eruptions associated with commencement of a new HIV antiretroviral regimen). However, a reaction suggestive of a potentially life-threatening situation should prompt immediate discontinuation of the drug, along with discontinuation of any interacting drugs that may slow the elimination of the suspected causative agent. Although the role of corticosteroids in the treatment of serious cutaneous reactions is controversial, most clinicians choose to start prednisone at a dosage of 1 to 2 mg/kg/day when symptoms are severe, except in patients with SJS or TEN. Antihistamines, topical corticosteroids, or both can be used to alleviate symptoms. Resolution of the reaction over a reasonable time frame after the drug is discontinued is consistent with a drug cause but also occurs for many infective and other causes of transient cutaneous eruptions. Patients should not be rechallenged if they have suffered a potentially serious reaction.

TABLE 40-3
Clinical Features That Warn of a Potentially Severe Drug Reaction

- Systemic
  - Fever and/or other symptoms of internal organ involvement such as pharyngitis, malaise, arthralgia, cough, and meningism
  - Lymphadenopathy
- Cutaneous
  - Evolution to erythroderma
  - Prominent facial involvement ± edema or swelling
  - Mucous membrane involvement (particularly if erosive or involving conjunctiva)
  - Skin tenderness, blistering or shedding
  - Purpura

PREVENTION

Cutaneous reactions to drugs are largely idiosyncratic and unexpected; serious

reactions are rare. Once a reaction has occurred, however, it is important to prevent future similar reactions in the patient with the same drug or a cross-reacting medication. For patients with hypersensitivity and severe reactions, wearing a bracelet (e.g., MedicAlert) detailing the nature of the reaction is advisable, and patient records should be appropriate labeled.

Host factors appear important in many reactions. Some of these can be inherited, which places first-degree relatives at a greater risk than the general population for a similar reaction to the same or a metabolically cross-reacting drug. This finding appears to be important in SJS, TEN, and drug hypersensitivity syndrome.

Reporting reactions to the manufacturer or regulatory authorities is important. Post-marketing voluntary reporting of rare, severe, or unusual reactions remains crucial to enhance the safe use of pharmaceutical agents.

CHAPTER 41

Pityriasis Rosea

Andrew Blauvelt

The term *pityriasis rosea* (PR) was first used by Gibert in 1860 and means pink (rosea) scales (pityriasis).[1] PR is a common acute, self-limited skin eruption that typically begins as a single thin oval scaly plaque on the trunk ("herald patch") and is typically asymptomatic. The initial lesion is followed several days to weeks later by the appearance of numerous similar-appearing smaller lesions located along the lines of cleavage of the trunk (a so-called *Christmas tree* pattern). PR most commonly occurs in teenagers and young adults, and is most likely a viral exanthem associated with reactivation of human herpesvirus 7 (HHV-7) and sometimes HHV-6.[1–4] Possible treatment may focus on associated pruritus. One study suggests that administration of high-dose acyclovir for 1 week hastens recovery from PR.[5]

EPIDEMIOLOGY

PR is reported in all races throughout the world, irrespective of climate.[6–8] The average annual incidence at one center was reported to be 0.16 percent (158.9 cases per 100,000 person-years).[8] Although PR is usually considered to be more common in the spring and fall months in temperate zones, seasonal variation has not been borne out in studies performed in other parts of the world. Clustering of cases can occur and has been used to support an infectious etiology for PR, although this is not a consistent feature observed in all communities.[7] Most studies have shown a slight female preponderance of approximately 1.5:1.[6,8] PR most commonly occurs between the ages of 10 and 35 years.[8] It is rare in both the very young (defined as less than 2 years) and the elderly (defined as older than 65 years). Recurrences of PR are rare, which suggests lasting immunity after an initial episode of PR.

ETIOLOGY AND PATHOGENESIS

Historically, PR has been considered to be caused by an infectious agent, given (1) the resemblance of the rash to known viral exanthems, (2) rare recurrences of PR that suggest lifelong immunity after one episode, (3) occurrence of seasonal variation in some studies, (4) clustering in some communities, and (5) the appearance of flu-like symptoms in a subset of patients. Numerous studies over the past 50 years have explored various pathogens as possible causes of PR. These pathogens have included numerous bacteria, fungi, and, most notably, viruses. Beginning with a study by Drago and colleagues in 1997,[2] most recent PR etiologic and pathogenetic studies have been focused on two ubiquitous HHVs, HHV-7 and HHV-6. Critical evaluation of the medical and scientific literature on PR reveals neither credible nor reproducible evidence that PR is associated with any pathogen other than HHV-7 and HHV-6.

PITYRIASIS ROSEA AT A GLANCE

- Common acute papulosquamous eruption normally lasting 4 to 10 weeks.
- Most often begins as a single 2- to 4-cm thin oval plaque with a fine collarette of scale located inside the periphery of the plaque ("herald patch"). Similar-appearing, but smaller, lesions then appear several days to weeks later and are typically distributed along the lines of cleavage on the trunk (in a "Christmas tree" pattern).
- Usually asymptomatic, but sometimes associated with pruritus and mild flu-like symptoms.
- Occurs most commonly in teenagers and young adults.
- Best scientific evidence supports the theory that pityriasis rosea represents a viral exanthem associated with reactivation of human herpesvirus 7 and sometimes human herpesvirus 6.
- Treatment is usually supportive, although mid-potency topical corticosteroids can be used for associated pruritus. One report suggests that administration of high-dose acyclovir for 1 week may hasten recovery from the disease.

The best scientific evidence suggesting that PR is a viral exanthem associated with reactivation of either HHV-7 or HHV-6 (and sometimes with both viruses) is strong.[2–4,9–11] In fact, the most definitive and compelling study on herpesviruses and PR was by Broccolo and colleagues in 2005.[3] Using sensitive and quantitative techniques, investigators have collectively shown that (1) HHV-7 DNA, and less commonly HHV-6 DNA, can be readily detected in cell-free plasma or serum samples from many patients with PR but not in serum or plasma from healthy individuals or patients with other inflammatory skin diseases; (2) HHV-7 messenger RNA and protein, and less commonly HHV-6 messenger RNA and protein, can be detected in scattered leukocytes found in perivascular and perifollicular regions within PR lesions but not in normal skin or skin from patients with other inflammatory skin diseases; (3) HHV-7– and HHV-6–specific immunoglobulin M antibody elevations in the absence of virus-specific immunoglobulin G antibodies do not occur in PR patients, whereas in primary viral infections elevation of immunoglobulin M antibodies alone is typical; and (4) HHV-7 and HHV-6 DNA are present in saliva of individuals with PR, which is not observed in those with a primary infection with these viruses. Taken together, these data strongly suggest that PR is a viral exanthem associated with systemic reactivation of HHV-7 and, to a lesser extent, HHV-6. Patients are viremic, which may explain associated flu-like symptoms in some patients, and they generally do not have infected epithelial cells or large viral loads within skin lesions, which explains the difficulty in detecting these viruses by electron microscopy and by non-nested polymerase chain reaction testing.

Despite these findings, there is still controversy over the role of HHV-7 and HHV-6 in the etiology of PR, because a number of studies with "negative" results have failed to support a causative role for HHV-7 and HHV-6 in this disease.[12–14] Whereas the studies with positive results have used the most sensitive, specific, and calibrated techniques for virologic studies and reports have been published in high-quality journals, the studies with negative results either used laboratory methods that were not particularly sensitive, calibrated, or quantifiable, or focused on peripheral blood mononuclear cells rather than cell-free plasma or serum.

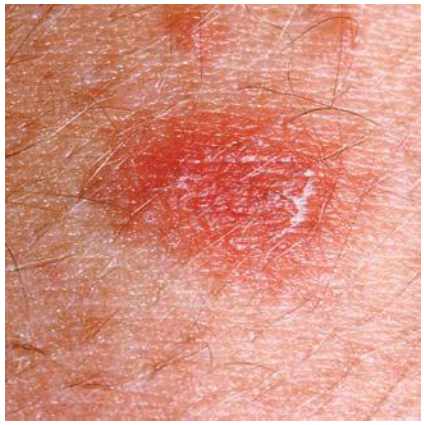
Correct interpretation of the recent viral literature on PR also requires proper understanding of the biology of HHV-7 and HHV-6. HHV-7 and HHV-6 are closely related β-herpesviruses, and the clinical diseases and biology associated with this group of herpesviruses are not as well studied as those of the α-herpesviruses (herpes simplex virus 1 and 2, varicella-zoster virus) and the γ-herpesviruses (Epstein-Barr virus and Kaposi sarcoma–associated herpesvirus). HHV-6 and HHV-7 are ubiquitous, with 90 percent of the U.S. population infected with HHV-6 by the age of 3 years[15] and 90 percent of the U.S. population infected with HHV-7 by the age of 5 years.[16] Unlike the α-herpesviruses, HHV-7 and HHV-6 do not infect keratinocytes but instead infect $CD4^+$ T cells within blood and are retained within these cells in a latent form in most individuals.[15–17] These cells are the likely source of cell-free viral DNA found in plasma or serum samples of patients with PR. They are also the likely source of the scattered perivascular and perifollicular virus-positive cells observed within some lesions of PR.[3,4]

It is important to note that the concept that PR represents a reactive viral exanthem containing few infected cells within skin lesions and viral reactivation within circulating blood $CD4^+$ T cells is perfectly analogous to that of the disease roseola, which is well accepted to be caused by primary infection with either HHV-6 or HHV-7[18,19] (see Chap. 192). In roseola, children are viremic and skin lesions generally do not contain infected cells.[20] Complete understanding of the role of HHV-7 and HHV-6 in the pathogenesis of PR is lacking at this time. For example, the mechanisms by which HHV-7 and HHV-6 are reactivated are unknown. As well, the characteristic distribution of lesions and differences in lesional and non-lesional skin are unexplained.

CLINICAL FINDINGS

History

In classic PR, patients usually describe the onset of a single truncal skin lesion followed several days to weeks later by the onset of numerous smaller lesions on the trunk. Pruritus is severe in 25 percent of patients with uncomplicated PR, slight to moderate in 50 percent, and absent in 25 percent. In a minority of patients, flu-like symptoms have been reported, including general malaise, headache, nausea, loss of appetite, fever, and arthralgias.



▲ **FIGURE 41-1** A typical primary plaque (herald patch) of pityriasis rosea, demonstrating an oval shape and fine scale inside the periphery of the plaque.

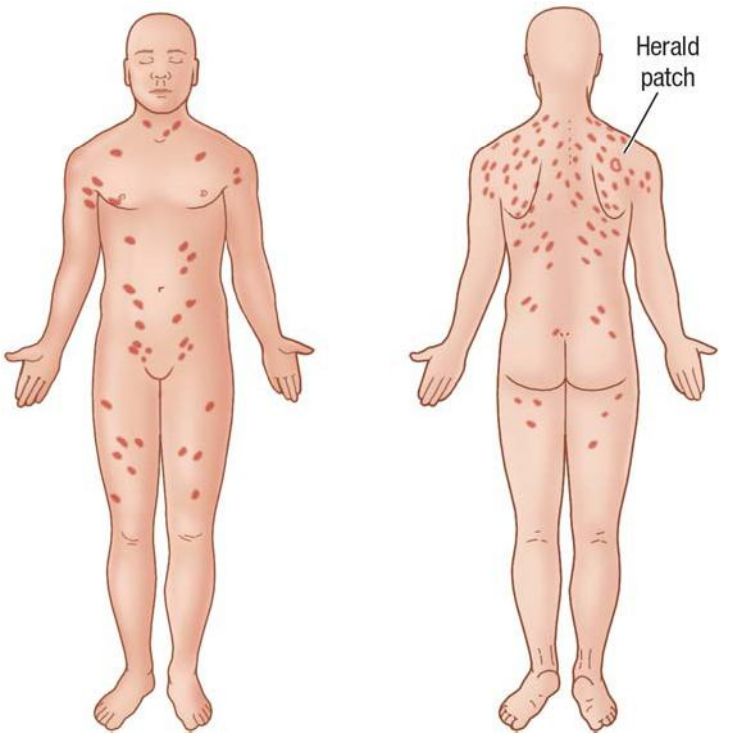
Cutaneous Lesions

The primary plaque of PR, or herald patch (Figs. 41-1, 41-2, 41-3 and see eFigs. 41-3.1 and 41-3.2 in on-line edition), is seen in 50 percent to 90 percent of cases. It is normally well demarcated; 2 to 4 cm in diameter; oval or round; salmon colored, erythematous, or hyperpigmented (especially in individuals with darker skin); and demonstrates a fine collarette of scale just inside the periphery of the plaque. When the plaque is irritated, it may have an eczematous papulovesicular appearance (see eFig. 41-3.3 in on-line edition). The primary plaque is usually located on the trunk in areas covered by clothes, but sometimes it is on the neck or proximal extremities. Localization on the face or penis is rare. The site of the primary lesion does not differ in males and females.

The interval between the appearance of the primary plaque and the secondary eruption can range from 2 days to 2

▲ **FIGURE 41-2** A non-scaly purpuric primary plaque (herald patch) of pityriasis rosea.

▲ **FIGURE 41-3** A double herald patch of pityriasis rosea.



▲ **FIGURE 41-4** Schematic diagram of the primary plaque (herald patch) and the typical distribution of secondary plaques along the lines of cleavage on the trunk in a Christmas tree pattern.

months, but the secondary eruption typically occurs within 2 weeks of the appearance of the primary plaque. At times, the primary and secondary lesions may appear at the same time. The secondary eruption occurs in crops at intervals of a few days and reaches its maximum in approximately 10 days. Occasionally, new lesions continue to develop for several weeks. The symmetric eruption is localized mainly to the trunk and adjacent regions of the neck and proximal extremities (Fig. 41-4). The most pronounced lesions extend over the abdomen and anterior surface of the chest as well as over the back (Figs. 41-5, 41-6, 41-7 and see eFigs. 41-6.1 and 41-6.2 in on-line edition). Lesions distal to the elbows and knees can occur but are less common. Two main types of secondary lesions occur: (1) small plaques resembling the primary plaque in miniature aligned with their long axes along lines of cleavage and distributed in a Christmas tree pattern, and (2) small, red, usually non-scaly papules that gradually increase in number and spread peripherally. Both types of lesions may exist concomitantly.

In approximately 20 percent of patients, the clinical picture diverges from the classic one described earlier. The primary plaque may be missing or present as double or multiple lesions (see Fig. 41-3 and see eFig. 41-3.1 in on-line edition), often close together. The primary plaque may be the sole manifestation of the disease or only one of two lesions (see eFig. 41-3.2 in on-line edition). The distribution of the secondary eruption may be exclusively peripheral. Facial involvement has been reported and occurs mainly in children. Localized forms of disease may involve certain body regions such as the scalp, axillae, vulva, and groin (see eFigs. 41-3.3 and 41-6.1 in on-line edition) and also may be localized to one side of the body.

The morphology of the secondary lesions may be atypical, and in these cases, the diagnosis of PR can be more challenging. Macules may occur and lack scaling, papules may be follicular, and typical plaques may be absent or resemble psoriasis (see eFig. 41-7.1 in on-line edition). The palms and soles are involved at times, and the clinical picture in these patients may simulate a widespread eczematous eruption. A vesicular type of PR (see eFig. 41-3.3 in on-line edition) is uncommon and usually affects children and young adults. Urticarial, pustular, purpuric (see Fig. 41-2 and see eFig. 41-7.2 in on-line edition), and erythema multiforme–like variants of PR also exist. These atypical forms of PR are not uniformly difficult to diagnose, because many patients will have classic plaques admixed with various atypical lesions, such as vesicles, follicular papules, and purpura.

▲ **FIGURE 41-5** Typical distribution of secondary plaques along the lines of cleavage on the back in a Christmas tree pattern.

▲ **FIGURE 41-6** Typical distribution of secondary plaques along the lines of cleavage on the chest of a black individual.

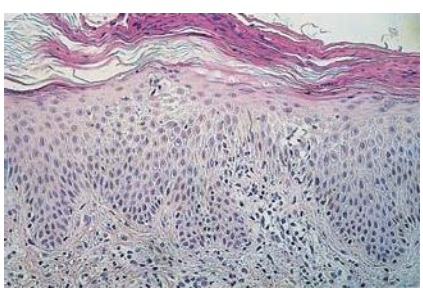
▲ **FIGURE 41-7** Vesicular pityriasis rosea, showing typical primary plaque and secondary papulovesicles. Note Christmas tree distribution.

Related Physical Findings

In rare cases enanthema may occur with hemorrhagic macules and patches, bullae on the tongue and cheeks, or lesions that resemble aphthous ulcers. Nail dystrophy after PR has also been reported. Lymphadenopathy may occur in patients with PR, especially early in the course of the disease and in association with flu-like symptoms.

LABORATORY TESTS

In cases of classic PR, most patients do not require skin biopsies because the diagnosis is straightforward on clinical grounds and the histologic findings are nonspecific. Typical histopathologic features include focal parakeratosis, a reduced or absent granular cell layer, mild acanthosis, mild spongiosis, papillary dermal edema, a perivascular and superficial dermal interstitial infiltrate of lymphocytes and histiocytes, and focal extravasation of erythrocytes (Fig. 41-8). Similar histologic findings are observed in both primary and secondary plaques. The histologic picture is indistinguishable from that of superficial gyrate erythema.



▲ **FIGURE 41-8** Typical nonspecific histologic features of pityriasis rosea, including patchy parakeratosis, absence of a granular cell layer, slight acanthosis, spongiosis, and a lymphohistiocytic infiltrate in the superficial dermis.

In older lesions, the perivascular infiltrate is often both superficial and deep, with less spongiosis and more pronounced acanthosis. These late lesions may be difficult to distinguish from psoriasis and lichen planus.

Routine blood studies usually give normal results and are not recommended. However, leukocytosis, neutrophilia, basophilia, lymphocytosis, and slight increases in erythrocyte sedimentation rate and levels of total protein, α_1- and α_2-globulins, and albumin have been reported.

DIFFERENTIAL DIAGNOSIS (Box 41-1)

Secondary syphilis may present with slightly scaly lesions and can mimic papular PR with no primary plaque. Mucosal lesions and lymphadenopathy may occur in both PR and syphilis, but as with involvement of the palms and soles, these findings are much more common in the latter. Serologic tests for syphilis will differentiate the two. Tinea corporis may resemble PR, especially when PR occurs as only a primary plaque or when it is localized to the groin area. Scaling will be at the periphery of the plaques in tinea corporis as opposed to inside the periphery of plaques in PR. Mycologic investigation is often necessary to rule out dermatophyte infection. The lesions of nummular dermatitis are usually round, not oval, and pinpoint papules and vesicles are more prominent than in PR. Guttate psoriasis may cause difficulties in diagnosing PR when only a few lesions are present, when lesions follow lines of cleavage, and when the disease course is chronic. Histologic examination may be useful in these cases. Pityriasis lichenoides chronica may present with a Christmas tree pattern on the trunk, but as a rule, typical lesions will be found on the extremities.

Box 41-1

Differential Diagnosis of Pityriasis Rosea (PR)

- **Secondary syphilis:** history of primary chancre, no herald patch is present, lesions typically involve palms and soles, condyloma lata may be present, usually more systemic complaints and lymphadenopathy, presence of plasma cells on histology. When in doubt, serologically test patient for syphilis (e.g., perform a Venereal Disease Research Laboratory test).
- **Tinea corporis:** scale is usually at periphery of plaques, plaques usually not oval and distributed along lines of cleavage. When in doubt, perform a KOH examination.
- **Nummular dermatitis:** plaques usually circular and not oval, no collarettes of scale, tiny vesicles common. When in doubt, perform a biopsy.
- **Guttate psoriasis:** plaques usually smaller than PR plaques and do not follow lines of cleavage, scale is thick and not fine. When in doubt, perform a biopsy.
- **Pityriasis lichenoides chronica:** longer disease course, smaller lesions, thicker scale, no herald patch is present, more common on extremities. When in doubt, perform a biopsy.
- **PR-like drug eruption:** see text for extensive list. When in doubt, obtain a drug history.

Many drugs have been reported to cause PR-like rashes. Thus, it is always important to obtain a drug history to investigate this possibility. These include arsenic, barbiturates, bismuth, captopril, clonidine, gold, interferon-α, isotretinoin, ketotifen, labetalol, organic mercurials, methoxypromazine, metronidazole, omeprazole, D-penicillamine, salvarsan, sulfasalazine, terbinafine, and tripelene amine hydrochloride. Of note, a more recent addition to this list is imatinib,[21] a drug used in the treatment of chronic myeloid leukemia. Drug-induced PR may be of the classic type, but it often shows atypical features, a protracted course, large lesions, subsequent marked hyperpigmentation, and transformation to lichenoid dermatitis.

COMPLICATIONS

Patients may experience flu-like symptoms, but these are relatively mild if they occur. No serious complications occur in PR patients.

PROGNOSIS AND CLINICAL COURSE

All patients with PR have complete spontaneous resolution of their disease. The disease duration normally varies between 4 and 10 weeks, with the first few weeks associated with the most new inflammatory skin lesions and the greatest likelihood of flu-like symptoms. Both post-inflammatory hypopigmentation and hyperpigmentation can follow PR. As with other skin diseases, this occurs more commonly in individuals with darker skin color, with hyperpigmentation predominating. Treatment with ultraviolet light phototherapy may also worsen post-inflammatory hyperpigmentation and

should be used with caution. Otherwise, patients have no residual effects secondary to the occurrence of PR. Recurrent disease is possible, but it is rare.

TREATMENT

Because PR is self-limited, there is no need for active treatment in uncomplicated cases. Patient education and reassurance is warranted in all cases. Midpotency topical corticosteroids may be used for symptomatic relief of pruritus. Interestingly, Drago and colleagues have reported that patients given high-dose acyclovir (i.e., 800 mg five times daily for 1 week) experienced more rapid resolution of PR than patients treated with placebo for 1 week.[5] Specifically, 79 percent of 42 patients had complete resolution of PR within 2 weeks of starting acyclovir therapy, whereas 4 percent of 45 patients treated with placebo experienced resolution of their disease at 2 weeks. Although patients were blinded to the type of treatment they received, the trial was limited in that the investigators were not blinded and the patients were not randomly assigned to one of the two treatment groups. Given that acyclovir and its derivatives are relatively inexpensive and well-tolerated drugs, this form of therapy should be considered in PR patients presenting early in their disease course who demonstrate associated flu-like symptoms and/or extensive skin disease. Several years ago, erythromycin was reported to be of benefit to patients with PR,[22] but clinical experience and a more recent report showing no efficacy of azithromycin in PR have not confirmed this initial result.[23] Some patients with PR may benefit from phototherapy,[24] although this should be used with caution given that it can increase the risk of post-inflammatory hyperpigmentation after disease resolution (Box 41-2).

Box 41-2

Treatment of Pityriasis Rosea

- For all patients: education about the disease process and reassurance
- For patients with associated pruritus: midpotency topical corticosteroids
- For patients early in the disease course who demonstrate associated flu-like symptoms and/or extensive skin disease: oral acyclovir 800 mg five times daily for 1 week (or equivalent acyclovir derivative) may hasten recovery from disease
- For selected patients: phototherapy may be useful

PREVENTION

There are no data on how PR can be prevented.

CHAPTER 42

Erythema Annulare Centrifugum and Other Figurate Erythemas

Walter H. C. Burgdorf

The figurate erythemas include a variety of eruptions characterized by annular and polycyclic lesions. Classification of this group has always been controversial; the literature abounds with contradictions, uncertainties and a bewildering array of synonyms. Darier in 1916 was the first to use the term *erythema annulare centrifugum* (EAC), although similar lesions had been described previously under other names.[1] Table 42-1 lists the figurate erythemas and the differential diagnoses to consider.

EPIDEMIOLOGY

EAC is an uncommon disorder. No epidemiologic data are available. There are only two large series in the literature: 66 cases identified clinically[2] and 73 first diagnosed histologically.[3] EAC appears to have no predilection for either sex or for any age group. Erythema gyratum perstans is an older synonym for familial EAC.

ETIOLOGY AND PATHOGENESIS

Almost certainly EAC is not a single disease but a clinical finding with many causes. Both the annularity and the peripheral spread of EAC have attracted speculation as to a possible mechanism. Most hypotheses have centered around interactions among inflammatory cells, their mediators, and ground substance as foreign antigens diffuse through the skin.[4,5]

ERYTHEMA ANNULARE CENTRIFUGUM AT A GLANCE

- Clinical pattern of annular expanding erythematous rings, which enlarge rapidly, fade, and then disappear, as new lesions appear.
- Diagnosis of erythema annulare centrifugum is one of exclusion.
- Superficial and deep variants can be separated clinically and histologically. Deep form is often lupus tumidus.
- No single cause.

TABLE 42-1
Migrating Erythemas

Disorder	Key Features	Chapter
Erythema annulare centrifugum (EAC)	Slowly migrating lesions; often idiopathic.	This chapter
Erythema gyratum repens	Rapidly moving; usually cancer mark.	154
Erythema migrans	Annular lesions originating from tick bite; skin sign of Lyme borreliosis.	187
Annular urticaria	Giant urticaria is annular and overlaps with EAC; patients have ordinary urticaria elsewhere and more pruritus.	37
Bullous pemphigoid	Early lesions often urticarial and may be annular.	54
Erythema multiforme	Target lesions, usually acral, often mucosal disease; some lesions annular.	38
Dermatophyte infections and tinea versicolor	Many fungal infections are annular (ringworm); they resemble superficial EAC but the scale contains hyphae or spores.	188, 189
Annular psoriasis	Pustular and occasionally ordinary psoriasis may have annular lesions.	18
Annular lupus erythematosus	Most common in neonatal form; Ro/La antibodies should be sought; overlaps with Sjögren syndrome (especially in Asians).	156
Erythema marginatum	Transient, rapidly spreading annular erythema; specific for rheumatic fever.	161
Necrolytic migratory erythema	Marker for glucagonoma; erosive perioral and acral lesions, but truncal lesions may be polycyclic.	154
Carrier state chronic granulomatous disease	Female carriers may have annular lupus erythematosus–like rash.	144
Hereditary lactate dehydrogenase M-subunit deficiency	Another rare genodermatosis with annular erythematous and scaly lesions.	This chapter
Familial annular erythema	Extremely rare.	This chapter
Annular erythema of infancy	Many different disorders; must rule out neonatal lupus erythematosus.	This chapter

The cause of most cases of EAC is unknown. In one series, 24 patients were closely evaluated, and in none of the cases was any definite cause found.[6] Bacterial or candidal infections are most often suspected as triggers.[7,8] Autoimmune diseases are also occasionally associated.[9] The hormonal changes of menses[10] or pregnancy have been implicated as well.[11] Although medications are often identified as causing EAC in case reports, none regularly induces such lesions.[12] EAC may be coupled with malignant neoplasms, with the eruption disappearing after treatment of the tumor and often returning as the tumor recurs.[13] This paraneoplastic marker must be distinguished from metastatic tumors with an annular pattern.[14]

CLINICAL FINDINGS

History

The history is most important in exploring the differential diagnostic considerations. In general the lesions are asymptomatic but may be cosmetically disturbing.

Cutaneous Lesions

EAC presents as one or more lesions that begin as erythematous macules or urticarial papules and enlarge by peripheral extension to form ringed, arcuate, or polycyclic figures (Fig. 42-1). They spread gradually to form large rings with central clearing, with the edges of the lesions often advancing several millimeters a day (see eFig. 42-1.1 in on-line edition). After a variable period of time, the lesions disappear, often to be replaced by new ones. In some cases annual recurrence has been described.[15]

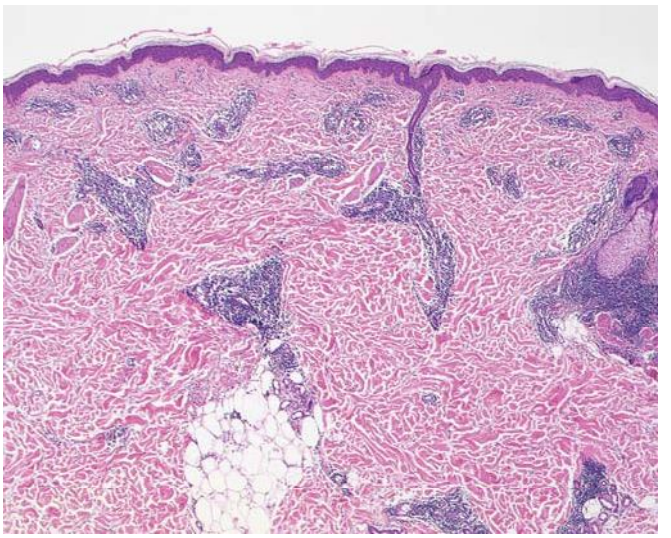
▲ **FIGURE 42-1** Superficial erythema annulare centrifugum. A large annular plaque with trailing scale behind the advancing erythematous edge.

Two sub-types of EAC can be identified both clinically and histologically[16]:

1. Superficial gyrate erythema has an indistinct border and trailing scale and may be pruritic (see Fig. 42-1, also see eFig. 42-1.1 in on-line edition).
2. Deep gyrate erythema has a firm yet indurated border, lacks scale, and is less often pruritic (Fig. 42-2, see eFig. 42-2.1 in on-line edition).

Additional findings may point to an underlying disorder, but most patients have no systemic signs or symptoms.

▲ **FIGURE 42-2** Deep erythema annulare centrifugum. Annular, slowly spreading lesions without scale, similar to urticaria but more long lived.



▲ **FIGURE 42-3** Deep erythema annulare centrifugum with normal epidermis and lymphocytic infiltrates about vessels of superficial and deep dermis. Many such lesions are lupus tumidus, so a careful search for mucin is mandatory. None is seen here. (Used with permission from Heinz Kutzner, Friedrichshafen, Germany.)

LABORATORY TESTS

Histopathology

Superficial EAC has epidermal changes of parakeratosis and spongiosis, with a superficial perivascular infiltrate (see eFigs. 42-2.2 and 42-2.3 in on-line edition). Deep EAC lacks epidermal damage and has intense lymphohistiocytic cuffing about both the superficial and deep vessels (Fig. 42-3). There is minimal papillary dermal edema and no spongiosis. One should search carefully for mucin as a clue to lupus erythematosus.

Other Laboratory Tests

There are no other laboratory tests diagnostic for EAC.

DIFFERENTIAL DIAGNOSIS (Box 42-1)

The differential diagnostic challenge in EAC is twofold. First one must exclude other eruptions that can appear similar, such as erythema migrans as the first sign of borreliosis (see Chap. 187) or erythema gyratum repens, which is generally more rapidly moving and usually reflects an underlying malignancy (see Chap. 154). In addition, there are diseases that can clinically present as EAC, but biopsy will provide a different answer. Included in this group are leukocytoclastic vasculitis, granulomatous disorders, metastases, and eosinophilic infiltrates.[17]

Then comes the problem of the many odd disorders that cause confusion, because they seem to have distinctive features but are rarely encountered (see Table 42-1). Prime examples are annular erythemas associated with the carrier state of chronic granulomatous disease[18] or a lactate dehydrogenase M-subunit deficiency.[19] There are also neutrophilic and lichenoid[20] variants of EAC. Familial EAC, originally described as erythema gyratum perstans, is rare.[21] Finally, there is the broad spectrum of annular erythemas of infancy,[22] including neonatal lupus erythematosus, *Malassezia furfur* infections, and the idiopathic variants which themselves may show eosinophilic or neutrophilic infiltrates,[23] as well as atrophy.[24]

Box 42-1

Differential Diagnosis of Erythema Annulare Centrifugum (EAC)

Most Likely

- Dermatophyte infections
- Tinea versicolor
- Erythema migrans
- Annular urticaria
- Lupus erythematosus
  - Lupus tumidus for deep EAC
  - Subacute lupus erythematosus for superficial EAC
- Annular psoriasis

Consider

- Erythema multiforme
- Granulomatous diseases (granuloma annulare, actinic granuloma, sarcoidosis)
- Bullous pemphigoid (urticarial phase)
- Leukocytoclastic vasculitis (especially in children)
- Erythema marginatum
- Erythema gyratum repens
- Necrolytic migratory erythema
- Hypereosinophilic syndrome
- Carrier state chronic granulomatous disease
- Hereditary lactase dehydrogenase M-subunit deficiency
- Familial annular erythema
- Annular erythemas of infancy

Always Rule Out

- Lupus erythematosus
- Underlying tumor or annular metastasis

PROGNOSIS AND CLINICAL COURSE

EAC tends to be a chronic disease, which waxes and wanes. The course is determined by associated diseases or triggers.

TREATMENT

Although an assiduous search for the underlying cause is the primary goal of treatment, only symptomatic relief is available. Systemic glucocorticoids usually suppress EAC, but recurrence is common when these drugs are stopped. Systemic therapy with antipruritics may help. Topical vitamin D analogues, perhaps combined with ultraviolet irradiation, are another option.[25,26] Empiric use of antibiotic, antifungal, or anti-candidal agents has sometimes been useful.[27] Biologics may represent yet another option.[28] In general, most of the therapeutic approaches used for chronic urticaria can also be tried for EAC.

CHAPTER 43

Granuloma Annulare

Julie S. Prendiville

Granuloma annulare is a benign self-limited disease, first described by Colcott-Fox[1] in 1895 and Radcliffe-Crocker[2] in 1902.

EPIDEMIOLOGY

Granuloma annulare is a relatively common disorder.[3] It occurs in all age groups but is rare in infancy.[3–5] The localized annular and subcutaneous forms occur more frequently in children and young adults. The generalized variant is more common in adults. Many studies report a female preponderance,[3] but some have found a higher frequency in males.[6] Granuloma annulare does not favor a particular race or geographic area, with the possible exception of the perforating type, which may be more common in Hawaii.[7]

Most cases of granuloma annulare are sporadic. Occasional familial cases are described with occurrence in twins, siblings, and members of successive generations.[3,8,9] Attempts to identify an associated HLA sub-type have yielded disparate results in different population groups.[10,11]

ETIOLOGY AND PATHOGENESIS

The etiology of granuloma annulare is unknown, and the pathogenesis is poorly understood. Most cases occur in otherwise healthy children. A variety of predisposing events and associated systemic diseases is reported, but their significance is unclear. It is possible that granuloma annulare represents a phenotypic reaction pattern with many different initiating factors.[12]

Predisposing Events

Non-specific mild trauma is considered a possible triggering factor because of the frequent location of lesions on the distal extremities of children. An early study of subcutaneous granuloma annulare found a history of trauma in 25 percent of children,[3] but this observation has not been replicated. Trauma is also a suspected factor in auricular lesions.[13] Granuloma annulare has occurred after a cat bite[14] and an octopus bite,[15] and insect bite reactions have been implicated.[3] There is a report of perforating granuloma annulare in long-standing tattoos.[16] Widespread lesions have developed after waxing-induced pseudofolliculitis[17] and erythema multiforme minor,[18] and in association with systemic sarcoidosis.[3,19] Severe uveitis without other evidence of sarcoidosis was found in eight patients with granuloma annulare.[20]

INFECTIONS AND IMMUNIZATIONS There are several reports of the development of granuloma annulare within herpes zoster scars, sometimes many years after the active infection.[21] It is also described after chickenpox.[22] Generalized, localized, and perforating forms of granuloma annulare may occur in association with human immunodeficiency virus (HIV) infection (see eFig. 43-0.1 in online edition).[23–28] Adenovirus was isolated from a lesion in one HIV-positive patient.[29] Epstein-Barr virus was excluded as a causative agent in these cases.[23,24] However, in other instances generalized granuloma annulare has been linked to viral infections, including Epstein-Barr virus infection,[30] chronic hepatitis B,[31] and hepatitis C.[32] Vaccinations for tetanus,[33] diphtheria toxoid,[34] and hepatitis B vaccination[35] have been implicated as triggering factors, although vaccination sites were spared in one case of generalized granuloma annulare.[36]

Lesions compatible with granuloma annulare may occur in patients with active tuberculosis.[12] There are also reports of granuloma annulare after tuberculin skin tests[3] and bacille Calmette-Guérin immunization.[37] Evidence of *Borrelia burgdorferi* infection was detected in two reports,[38,39] but this association was not confirmed in a serologic study.[40] A case in which chronic relapsing granuloma annulare flared during scabies infestation was attributed to the Koebner phenomenon.[41]

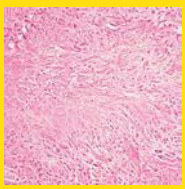
SUN EXPOSURE Granuloma annulare with a predilection for sun-exposed areas[42–44] and seasonal recurrence[42] has been described. Photosensitive granuloma annulare has been observed in patients with HIV infection.[45] One patient developed generalized disease after psoralen plus ultraviolet A light therapy,[46] but it is of note that phototherapy and psoralen/ultraviolet A phototherapy have also been used to treat generalized granuloma annulare.[47–50]

Actinic granuloma, also known as *annular elastolytic giant cell granuloma*, develops on photodamaged skin and is believed to represent a granulomatous reaction to actinic elastosis.[51] Its relationship to granuloma annulare is debated.

DRUGS Granuloma annulare–like drug reactions are reported for gold therapy and treatment with allopurinol, diclofenac, quinidine, intranasal calcitonin, and amlodipine.[52] An interstitial granulomatous drug reaction linked to the use of angiotensin-converting enzyme inhibitors, calcium channel blockers, and other medications is considered a distinct entity but may mimic granuloma annulare.[53,54]

DIABETES MELLITUS AND THYROID DISEASE Development of granuloma annulare in patients with diabetes mellitus is extensively documented. Whether this is a true relationship has long been debated. The link is primarily with type 1 insulin-dependent diabetes,[55] but cases are also reported with type 2 non–insulin-dependent disease.[56–58] Localized[55] and generalized[43,58,59] as well as subcutaneous nodular[56,60,61] and perforating[5,7] forms of granuloma annulare have been observed. Granuloma annulare rarely pre-dates the onset of diabetes.[55,61] The histopathologic similarity between granuloma an-

GRANULOMA ANNULARE AT A GLANCE



- Relatively common disorder; exact prevalence is unknown; favors children and young adults.
- A localized ring of beaded papules on the extremities is typical; generalized, subcutaneous, perforating, and patch subtypes also occur.
- The cause is unknown, and the pathogenesis is poorly understood.
- Pathologic features consist of granulomatous inflammation in a palisaded or interstitial pattern associated with varying degrees of connective tissue degeneration and mucin deposition.
- Most cases resolve spontaneously within 2 years.

▲ **FIGURE 43-1** **A.** Typical annular lesion of granuloma annulare on a finger. **B.** A larger annular lesion of granuloma annulare on the dorsum of the hand.

nulare and necrobiosis lipoidica diabeticorum and the co-existence of both conditions in occasional diabetic patients[57] suggest a true association. However, most patients with granuloma annulare do not have diabetes mellitus. Studies attempting to establish a causal correlation have yielded conflicting results.[55,62,63]

Granuloma annulare has also occurred in a number of patients with thyroiditis, hypothyroidism, and thyroid adenoma.[59,64–67]

MALIGNANCY An association between granuloma annulare and malignancy in adult patients is reported primarily with Hodgkin and non-Hodgkin lymphoma, including mycosis fungoides, Lennert lymphoma, B-cell disease,[68–71] and T-cell large cell lymphocytic leukemia.[72] It is reported less commonly with solid tumors, particularly of the breast.[43,68] The skin lesions of cutaneous lymphoma and other hematologic malignancies may mimic granuloma annulare both clinically and histopathologically.[73,74] It may be difficult to distinguish whether they represent true granuloma annulare with atypical lymphocytes, or cutaneous lymphoma obscured by a granulomatous infiltrate.[70,71]

Pathogenetic Mechanisms

The pathogenetic mechanisms that result in foci of altered connective tissue surrounded by a granulomatous inflammatory infiltrate are not understood. Proposed mechanisms include (1) a primary degenerative process of connective tissue initiating granulomatous inflammation,[75] (2) a lymphocyte-mediated immune reaction resulting in macrophage activation and cytokine-mediated degradation of connective tissue,[27,76–80] and (3) a subtle vasculitis or other microangiopathy leading to tissue injury.[76]

CLINICAL FINDINGS

History

The typical history is of one or more papules with centrifugal enlargement and central clearing. These annular lesions are often misdiagnosed as tinea corporis and treated unsuccessfully with topical antifungal agents. Subcutaneous nodules may raise suspicion about malignancy or rheumatoid disease.

Granuloma annulare is usually asymptomatic. Mild pruritus may be present, but painful lesions are rare.[81,82] Nodular lesions on the feet may cause discomfort from footwear.[83] Cosmesis is often a concern for adolescent and adult patients, particularly with generalized disease.

Cutaneous Lesions

Clinical variants of granuloma annulare include the localized, generalized, subcutaneous, perforating, and patch types. Linear granuloma annulare,[84] a follicular pustular form,[85] and papular umbilicated lesions in children[86] have also been described. There is overlap between the different variants, and more than one morphologic type may co-exist in the same patient.

LOCALIZED TYPE The most common form of granuloma annulare is an annular or arcuate lesion. It may be skin colored, erythematous, or violaceous. It usually measures 1 to 5 cm in diameter.[3] The annular margin is firm to palpation and may be continuous or consist of discrete or coalescent papules in a complete or partial circle (Fig. 43-1). The epidermis is usually normal, but surface markings may be attenuated over individual papules. Within the annular ring, the skin may have a violaceous or pigmented appearance. Solitary firm papules or nodules may also be present. Papular lesions on the fingers may appear umbilicated.

The dorsal hands and feet, ankles, lower limbs, and wrists are the sites of predilection (see Figs. 43-1, 43-2). Less commonly, lesions occur at other sites, including the eyelids.[87] The palms and soles are occasionally involved.[81,82] Localized annular lesions may co-exist with the subcutaneous or patch forms.

GENERALIZED TYPE The generalized form of granuloma annulare is said to comprise 8 percent to 15 percent of cases.[3,43] The majority of patients are adult, but it may be seen in childhood.[43,88] Unlike in localized disease, the trunk is frequently involved, in addition to the neck and extremities. The face, scalp, palms, and soles may also be affected.[43]

Generalized granuloma annulare presents as widespread papules (Fig. 43-3A), some of which coalesce to form small annular plaques or larger discolored patches with raised arcuate and serpiginous margins (see Fig. 43-3B). Lesions may be skin colored, pink, violaceous, tan, or yellow. An annular or non-annular morphology may predominate.[43] A generalized form of perforating granuloma annulare has also been described.[5,7]

SUBCUTANEOUS TYPE The subcutaneous form of granuloma annulare occurs

▲ **FIGURE 43-2** Localized granuloma annulare with nodule on the hand of a child.

▲ **FIGURE 43-3** **A.** Generalized granuloma annulare. Small papular lesions that are too small to exhibit annular configuration. **B.** Multiple annular lesions on the lower arm.

predominantly in children[89,90] but is also described in adult patients.[91–93] It is characterized by firm to hard, usually asymptomatic nodules located in the deep dermis and subcutaneous tissues. They may extend to underlying muscle, and nodules on the scalp and orbit are often adherent to the underlying periosteum.

Individual lesions measure from 6 mm to 3.5 cm in diameter.[90,94] They are distributed most often on the anterior lower legs in a pretibial location.[89] Other sites of predilection are the ankles, dorsal feet, buttocks, and hands.[93,95] Nodules on the scalp,[94,96] eyelids,[97–99] and orbital rim[60,100,101] may present a diagnostic challenge. Subcutaneous granuloma annulare may also be found on the penis.[102]

PERFORATING TYPE The perforating type of granuloma annulare is a rare variant characterized by trans-epidermal elimination of the necrobiotic collagen. It may be localized, usually to the dorsal hands and fingers (see eFig. 43-3.1 in on-line edition), or generalized over the trunk and extremities.[5,7] It has been described on the ears[103] and within herpes zoster scars and tattoos.[16] Superficial small papules develop central umbilication or crusting, and there may be discharge of a creamy fluid. Lesions heal with atrophic or hyperpigmented scars. In one series, 24 percent of patients complained of pruritus and 21 percent of pain.[104] Papular umbilicated granuloma annulare on the hands of children[86] and a generalized follicular pustular type of granuloma annulare[85] may be clinical variants.

PATCH TYPE Macular lesions that present as erythematous, red-brown, or violaceous patches without an annular rim are reported in adult women.[80,105] An arcuate dermal erythema is also observed. Generalized confluent erythema has been described in an HIV-positive patient.[27]

Related Physical Findings

Most patients with granuloma annulare are healthy and have no other abnormal physical findings. Arthralgia is reported in association with painful lesions on the hands.[82] Granuloma annulare–like skin lesions and joint disease characterize a multisystem disorder described as interstitial granulomatous dermatitis with arthritis.[106]

Oral involvement was observed in one patient with HIV-associated disease.[24]

LABORATORY TESTS

A diagnosis of localized annular granuloma annulare is made on clinical examination, and further evaluation is rarely indicated. Biopsy to obtain a specimen for histopathologic examination is necessary when the presentation is atypical, when lesions are symptomatic, and when the diagnosis is otherwise in doubt. Histopathologic analysis may be required to confirm a diagnosis of generalized granuloma annulare or subcutaneous nodular disease on the head and orbital region.

Histopathologic Findings

The diagnosis is best made at low magnification. Changes are usually observed in the upper and middle dermis, although any part of the dermis or subcutis can be involved. The characteristic histopathologic finding is a lymphohistiocytic granuloma associated with varying degrees of connective tissue degeneration and mucin deposition. The inflammatory infiltrate may have a palisaded or interstitial pattern, or a mixture of both patterns.[107–109] Occasionally, a sarcoid-like pattern with large epithelioid histiocytes is seen.[107]

The typical appearance is of single or multiple foci of inflammation with a central core of altered collagen (necrobiosis) surrounded by a wall of palisaded histiocytes (Fig. 43-4). The necrobiotic centers are usually oval, slightly basophilic, devoid of nuclei, and marked by a loss of definition of the collagen bundles and diminished or absent elastic tissue fibers. Stains for mucin and lipid often give positive results.

Box 43-1

Differential Diagnosis of Granuloma Annulare

ANNULAR TYPE

Consider

- Tinea corporis
- Subacute cutaneous lupus erythematosus
- Neonatal lupus erythematosus
- Annular lichen planus
- Acute febrile neutrophilic dermatosis
- Erythema chronicum migrans
- Actinic granuloma
- Necrobiosis lipoidica diabeticorum

Rule Out

- Infections (e.g., tuberculosis, atypical mycobacteria, syphilis)
- Interstitial granulomatous dermatitis with arthritis
- Interstitial granulomatous drug reaction
- Annular sarcoidosis
- Lymphoma

GENERALIZED TYPE

Consider

- Lichen planus
- Lichen nitidus
- Molluscum contagiosum

Rule Out

- Lichenoid and granulomatous dermatitis of acquired immunodeficiency syndrome
- Infections (e.g., tuberculosis, atypical mycobacteria, syphilis)
- Sarcoidosis
- Blau syndrome (familial granulomatous arthritis, skin eruption, and uveitis)
- Interstitial granulomatous drug reaction
- Lymphoma

SUBCUTANEOUS TYPE

Consider

- Erythema nodosum
- Dermoid cyst
- Rheumatoid nodules

Rule Out

- Epithelioid sarcoma
- Benign or other malignant tumors
- Deep infections

PERFORATING TYPE

Consider

- Molluscum contagiosum
- Insect bites
- Pityriasis lichenoides
- Perforating collagenosis and other perforating disorders
- Foreign body granuloma
- Papulonecrotic tuberculid
- Palisaded neutrophilic and granulomatous dermatitis of immune complex disease

PATCH TYPE

Consider

- Morphea
- Erythema annulare centrifugum
- Parapsoriasis

Rule Out

- Lymphoma

Immunofluorescence testing may show deposition of fibrin, immunoglobulin M, and C3 as a variable finding around vessel walls or at the basement membrane zone; immunoglobulin M cytoid bodies are also reported.[106] Ultrastructural changes in the connective tissue and capillaries have been described.[75]

Special Tests

A diagnosis of granuloma annulare is made clinically or by skin biopsy. Special investigations are usually not necessary. Further evaluation to rule out systemic disease such as infection, sarcoidosis, or malignancy may be required in atypical cases of granuloma annulare.[12,72–74,82,105] Investigation for endocrine disease is indicated if the patient has signs or symptoms of diabetes or thyroid dysfunction.

Imaging studies may be performed in subcutaneous granuloma annulare when the clinical features are not recognized or when the presentation is atypical with rapid enlargement or pain.[112] Radiographs show a non-specific soft tissue mass without calcification or bone involvement. Ultrasonographic examination reveals a hypoechoic area in the subcutaneous tissues. Magnetic resonance imaging shows a mass with indistinct margins, isointense or slightly hyperintense to muscle with T1-weighted images and with a heterogeneous but predominantly high signal intensity on T2-weighted images.[112]

DIFFERENTIAL DIAGNOSIS

See Box 43-1.

TREATMENT

See Box 43-2.

Box 43-2

Treatment Options for Granuloma Annulare

- Await spontaneous resolution
- Apply topical corticosteroid with or without occlusion
- Administer intralesional triamcinolone 2.5 mg/mL[113]

ANECDOTAL REPORTS OF BENEFIT

- Topical
  - Tacrolimus 0.1% ointment[114]
  - Pimecrolimus cream[115]
  - Imiquimod 5% cream[116,117]
- Intralesional
  - Interferon-γ[118]
  - Interferon-β[118]
  - Sterile water or saline[113]
- Systemic
  - Antimalarials[88]
  - Retinoids[119–123]
  - Corticosteroids[83,98]
  - Cyclosporin[72,124]
  - Zileuton with vitamin E[125]
  - Chlorambucil, niacinamide, potassium iodide, fumaric acid esters, dapsone[3,43,83]
  - Etanercept[126]
  - Infliximab[127]
  - Efalizumab[128]
- Other
  - Phototherapy[47–50]
  - Skin biopsy[129]
  - Cryotherapy[130]
  - Pulsed dye or CO_2 laser[131,132]

CLINICAL COURSE AND PROGNOSIS

Most cases of localized granuloma annulare resolve spontaneously without sequelae. Lesions may clear within a few weeks or persist for several years. The majority disappear within 2 years.[83] Recurrent lesions may develop months or even years later, frequently at the same site. Generalized granuloma annulare often runs a more protracted course.[43] Perforating granuloma annulare results in scarring.[104] There is one report of anetoderma and mid-dermal elastolysis after generalized granuloma annulare.[44]

SECTION 7

DISORDERS OF EPIDERMAL DIFFERENTIATION AND KERATINIZATION

CHAPTER 44

Epidermal Growth and Differentiation

Stanley J. Miller
Tung-Tien Sun
Pierre A. Coulombe

THE EPIDERMIS: AN OVERVIEW

The lifelong proliferation of the epidermis and its long-term maintenance require interfollicular stem cells and molecular regulators of epidermal growth and differentiation. This chapter focuses on epidermal stem cells, keratin filaments that are synthesized as major epidermal specialization products, keratohyalin granules, and the cornified envelope (CE).

EPIDERMAL GROWTH

Epidermal Stem Cells

Like all epithelia, the epidermis undergoes a constant process of self-renewal. Proliferation is initiated by a stem cell and occurs primarily in the basal layer.[1] A highly orchestrated program of terminal differentiation begins with keratinocytes exiting into the suprabasal layers, culminating in the production of superficially located cornified cells, which, in essence, consist largely of highly disulfide–cross-linked and aggregated keratin fibers wrapped in an impenetrable CE. This outermost cell layer, the stratum corneum, is the ultimate product of interfollicular epidermal differentiation, and is largely responsible for the skin's barrier function against water loss and environmental insults.

In all epithelia, an underlying homeostatic system exists to replace terminally differentiated cells and tissue loss after injury. This hierarchical system typically involves several stages of cells that have decreasing reproductive capacity and increasing commitment to differentiation (Fig. 44-1). The most primordial cell in the hierarchy, the stem cell, has the ability to reproduce for the entire life span of the organism. It is relatively undifferentiated, divides infrequently, and often resides in a specialized physical locale termed a *niche*. After division, a stem cell gives rise to, on average, one daughter stem cell that remains in the stem cell niche and another, termed a *transit-amplifying (TA) cell*, that leaves the stem cell niche. These rapidly proliferating cells undergo further reproductive divisions, and their offspring both expand the population of cells arising from the initial stem cell mitosis and progressively commit irreversibly to differentiation along one or several lineages. Our knowledge of stem and TA cell location and functioning in the interfollicular epidermis is incomplete. Nevertheless, there exists a framework of understanding,[1,2] which will undoubtedly be revised and clarified by future studies.

Epidermal Proliferative Units

Interfollicular epidermal stem cells reside at the base of organized, hexagonal columns of cells designated *epidermal proliferative units* (EPUs) (Fig. 44-2). The interdigitating, repetitive columnar organization of mouse skin was first noted by Mackenzie in 1970,[3] and our understanding of EPU structure has changed little since its initial description by Potten in 1974.[4] The basal layer of each functionally independent and self-renewing EPU consists of approximately 10 cells. A single epidermal stem cell lies at the center, with TA cells surrounding it. Under normal homeostatic conditions, epidermal proliferation occurs in this basal layer, and exit of TA cells into the suprabasal layer is accompanied by their commitment to terminal differentiation. The presence of EPUs has been described in the skin of some body sites for both mouse[5–7] and human[8–10] skin. The existence of functional differences between the centrally located stem cells and the peripherally located TA cells within individual EPUs[11,12] has been demonstrated by a variety of techniques. At a macroscopic

EPIDERMAL GROWTH AND DIFFERENTIATION AT A GLANCE

- The interfollicular epidermis is maintained by a population of stem cells.
- Slow-cycling stem cells give rise to transit-amplifying cells, which yield terminally differentiated cells.
- Abnormalities in epidermal stem cells may be involved in pathogenesis of skin cancers and other proliferative epidermal diseases.
- Epidermal differentiation is accompanied by orchestrated expression of keratins and subunits of cornified envelope.
- Keratins contribute to the mechanical stability and pliability of the epidermis.
- Mutations in major epidermal differentiation products are underlying causes of important skin diseases.

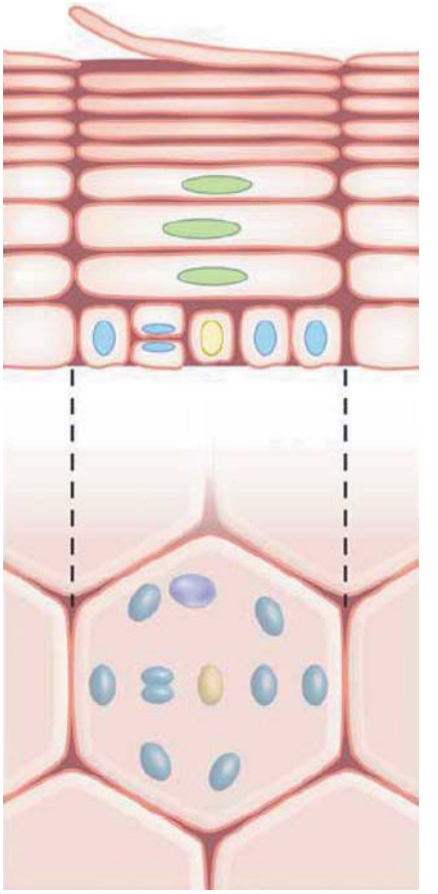
▲ **FIGURE 44-1** The proliferative hierarchy in epithelia: the stem cell concept. The ultimate progenitor cells are termed *stem cells*. They are slow cycling, long-lived, phenotypically undifferentiated, reside in specialized microenvironments, and constitute only a small percentage of the total epithelial cell population. Stem cell division produces transit amplifying or committed progenitor cells, which cycle rapidly and produce a clonal expansion of the offspring arising from an initial stem cell division. These cells eventually become the mature, terminally differentiated cells that constitute the bulk of a given epithelial population. Numbers indicate generation.



▲ **FIGURE 44-2** Functional organization of interfollicular epidermis: the epidermal proliferative unit (EPU) concept. Interfollicular epidermis of the skin of certain body sites is histologically organized into columns termed *EPUs*; each consists of approximately 10 basal cells, including a single putative stem cell (*yellow*), its immediate transit-amplifying cell progeny (*blue*), and early-differentiating cells (*purple*). More differentiated keratinocytes (*green*) and then mature enucleated squames lie directly above them, in an ordered stack rising above the basal layer. EPUs represent functionally independent packets of self-renewing interfollicular epidermis that are ultimately dependent on a single putative stem cell for lifelong cell production. Constant self-renewal within the basal layer of skin compensates for the continual loss of differentiated squames from its surface. (Reprinted/adapted from Kaur P: Interfollicular epidermal stem cells: Identification, challenges, potential. *J Invest Dermatol* **126**:1452, 2006.)

level, EPU size in human skin has been suggested be approximately 2 mm.[13]

Relative Location of Epidermal Stem Cells in the Rete Ridges

Whether epidermal stem cells are uniformly dispersed (as single cells at the bottom of EPU, or as clusters; see Lateral Migration), or concentrated in certain areas of the skin is controversial. Initial studies of monkey palm epidermis by Lavker and Sun in 1982 suggest an enrichment of putative stem cells at the base of rete ridges,[14] whereas later examination of the expression of β1-integrin (a putative stem cell marker; see Markers for the Interfollicular Epidermal Stem and Transit Amplifying Cells) in human foreskin and scalp localized the presumptive stem cells to the tops of dermal papillae.[8] A recent study using retroviral transduction of fluorescent marker protein into human foreskin xenografts grown on the backs of athymic mice found epidermal stem cells located at all levels throughout the undulating basal layer.[10] It is therefore possible that, in human skin, regional differences exist in the relative distribution of interfollicular epidermal stem cells.

Asymmetric versus Symmetric Division of the Epidermal Stem Cells

The logistics of epidermal cell division are still not clearly understood. Within the scheme of "stem cell → TA cell → terminally differentiated cell," epidermal proliferation is initiated by the division of a stem cell and then expanded by subsequent divisions of TA cells. The initial stem cell division may be asymmetric, yielding one stem cell and one TA cell that is destined to exit from the stem cell niche, or symmetric, yielding two identical stem cell or TA cell progeny. Invariant, asymmetric stem cell division is more common in unicellular organisms and invertebrates. A structured three-dimensional niche (a so-called *lineage niche*[15]) is typically required to partition the two different offspring. For example, in the Drosophila ovary, the daughter stem cell remains associated with somatic ("cap") cells of the basal terminal filament, whereas the committed daughter cell is displaced from the niche and differentiates into a mature egg.[16] Symmetric division is more common in mammals, with extrinsic stimuli regulating the final size of stem and committed progenitor populations.[17] Recent research suggests that asymmetric division may also occur in the basal cell layer of epidermis.[18] One interesting implication is that, during each round of asymmetric stem cell division, selective segregation of the original DNA

into the daughter cell that is destined to remain a stem cell may provide a mechanism to protect the stem cell genome from accumulating mutations and subsequent cancer formation.[19] It has therefore been suggested that epidermal stem cells have the ability to divide in both an asymmetric and symmetric fashion. During development, when an increased number of stem cells are required—and perhaps during wound healing in adult life as well—epidermal stem cells follow a symmetric program of division that expands their population.[13] During times of homeostasis in mature epidermis, asymmetric division may predominate.[18] TA cells are generally thought to divide symmetrically, producing either two daughter TA cells or two postmitotic cells, but they may have the ability to alter their divisional programs as well.[20] A complex regulatory system could use these two modes of division, frequency of stem cell division, total number of TA cell divisions, and duration of both stem and TA cell cycle times to maintain the integrity of epidermis and other stratified squamous epithelia in the face of various physiologic requirements[21] (see eFig. 44-2.1 in on-line edition).

Lateral Migration

Although the epidermis is traditionally thought of as consisting of vertically oriented, self-contained columns or units of replication,[5,10] some studies suggest that lateral movement between and beyond these individual columns may occur. In sun-exposed skin, Brash and colleagues[22] have identified clonal patches of keratinocytes, each containing a single p53 mutation, that are many cells in size. During wound healing, an organized lateral migration of proliferating cells occurs, that is then followed, once healing is completed, by reconstitution of new epidermal columns and re-establishment of a program of vertical differentiation.

Stratification

Under normal homeostatic conditions, the process of differentiation begins at the time of exit from the basal layer. Approximately 8 percent of basal cells are positive for markers of differentiation (such as keratins 1/10),[24] and these cells are usually connected to the basement membrane by a thin stalk and are mushroom-shaped in cross-section[12] indicating they are in the process of exiting vertically from the basal layer compartment. The mechanisms that initiate the processes of differentiation and stratification are unclear. Stratification, which begins with exit from the basal layer, may be initiated by the onset of differentiation[25] and assisted by actin dynamics within the cytoskeletal architecture of the overlying suprabasal layers.[26] It appears from whole-mount labeling experiments that the process of differentiation, as evidenced by K10 keratin expression, begins within the TA compartment.[24] Recently, it has been suggested that oriented, asymmetric division within the basal cell layer initiates both stratification and differentiation in mammalian epidermis.[18]

Relationship between Stem Cells in Various Compartments in Skin Epithelia

Follicular stem cells are located in the region of the bulge (see Chap. 84)[27] and were initially hypothesized to serve as an "ultimate reservoir" of stem cells for the interfollicular epidermis.[28] However, it is now clear that the interfollicular epidermis and hair follicle bulge contain separate and distinct stem cell populations, each responsible for the maintenance of their terminally differentiated keratinocyte populations. Bulge stem cells do not appear to contribute to the interfollicular epidermis during periods of homeostasis.[7,29,30] Progenitor cells migrate from the follicular bulge to sites of interfollicular epidermal wounding, but the migration appears to involve TA cells,[7] and their presence in the new epidermis appears to be temporary and short-lived. It has also recently been shown that bone marrow–derived stem cells do not function adequately as a source of interfollicular keratinocytes during steady-state homeostasis or after wounding.[31]

Markers for the Interfollicular Epidermal Stem and Transit Amplifying Cells

Unfortunately, reliable markers for interfollicular stem and TA cells do not yet exist. Recent work has identified many candidate markers for follicular bulge stem cells (see Chap. 84)[32,33] but their applicability to interfollicular epidermal stem cells remains unknown. This is an area of intense, ongoing research. Even the precise number of stem cells present in the interfollicular epidermis remains uncertain; original kinetic studies in mice indicated that stem cells represent approximately 10 percent of the basal cell layer,[4] whereas more recent label-retaining[11] and transgenic mouse[7] studies suggest a 1 percent presence. Of interest is a recent study that performed single cell gene expression profiling of interfollicular stem and TA cells.[36] Fourteen putative stem cell markers were discovered, including an epidermal growth factor receptor antagonist named *Lrig1*.

Regulatory Mediators

As with stem cell markers, the study of regulatory mediators of interfollicular epidermal homeostasis is the focus of ongoing research efforts.[37] Although frequently complex and overlapping, regulatory mediators may be somewhat artificially divided into four broad categories. First are the stimuli that direct progenitor cells towards specific terminal differentiation pathways (e.g., follicular vs. interfollicular vs. sebaceous structures; stratified squamous vs. simple columnar epithelium). Second are the microenvironmental features of the niche that maintain stem cell presence. Third are mediators that alter proliferation, often through focal and differing effects on the stem and TA cell populations. Fourth are regulators that stimulate or inhibit a commitment to terminal differentiation.

Several pathways appear to be involved in stem cell homeostasis and function. p63 has been suggested to be involved in epidermal stem cell maintenance,[47] although the details are not yet clear.

Diseases Related to Proliferative Dysfunction

A number of skin diseases appear to be related to stem or TA cell dysfunction. One example of an epidermal stem cell–related disease is skin cancer.[59] A stem cell model of cancer views tumor growth as an aberrant version of normal tissue homeostasis.[60] Although the end product is not a normally differentiated cell, owing to the multiple genetic mutations present, the process of cancerous growth appears in many instances to recapitulate the "stem cell → TA cell → differentiated cell" procession that occurs during normal tissue homeostasis. As in normal tissues, only a small percentage of the tumor population (the "cancer stem cells") maintain the capacity for long-term proliferation.[60] Cancer stem cells arise slowly from normal stem cells over time, because they are the only cells that per-

sist in an organ for the months and years necessary to acquire the multiple genetic mutations required to produce a malignancy (see Chap. 112).[59]

An epidermal disease that may represent an example of TA cell dysfunction is psoriasis (see Chap. 18). In addition to inflammatory and dermal changes, there appears to be a large increase in the β1-integrin–dim (TA cell) keratinocyte population in psoriasis, extending up into the suprabasal layers, with greatly increased proliferative activity as measured by Ki67 expression.[61,62] Further, C-myc, which is thought to stimulate conversion of epidermal stem to TA cells,[48] is upregulated in psoriasis.[63]

Gene Therapy

Because it is so accessible, the epidermis is an attractive target for gene therapy. This field of endeavor has tremendous potential but is still in its infancy. A number of technical issues remain unresolved.[64] The organization of skin into vertical proliferative units poses potential limits to the lateral spread of genetic manipulation, and to be long lasting, the epidermal stem cells must be the ultimate targets of therapy. Nevertheless, many advances in this arena are likely in the coming years.

KERATINS AND EPIDERMAL DIFFERENTIATION

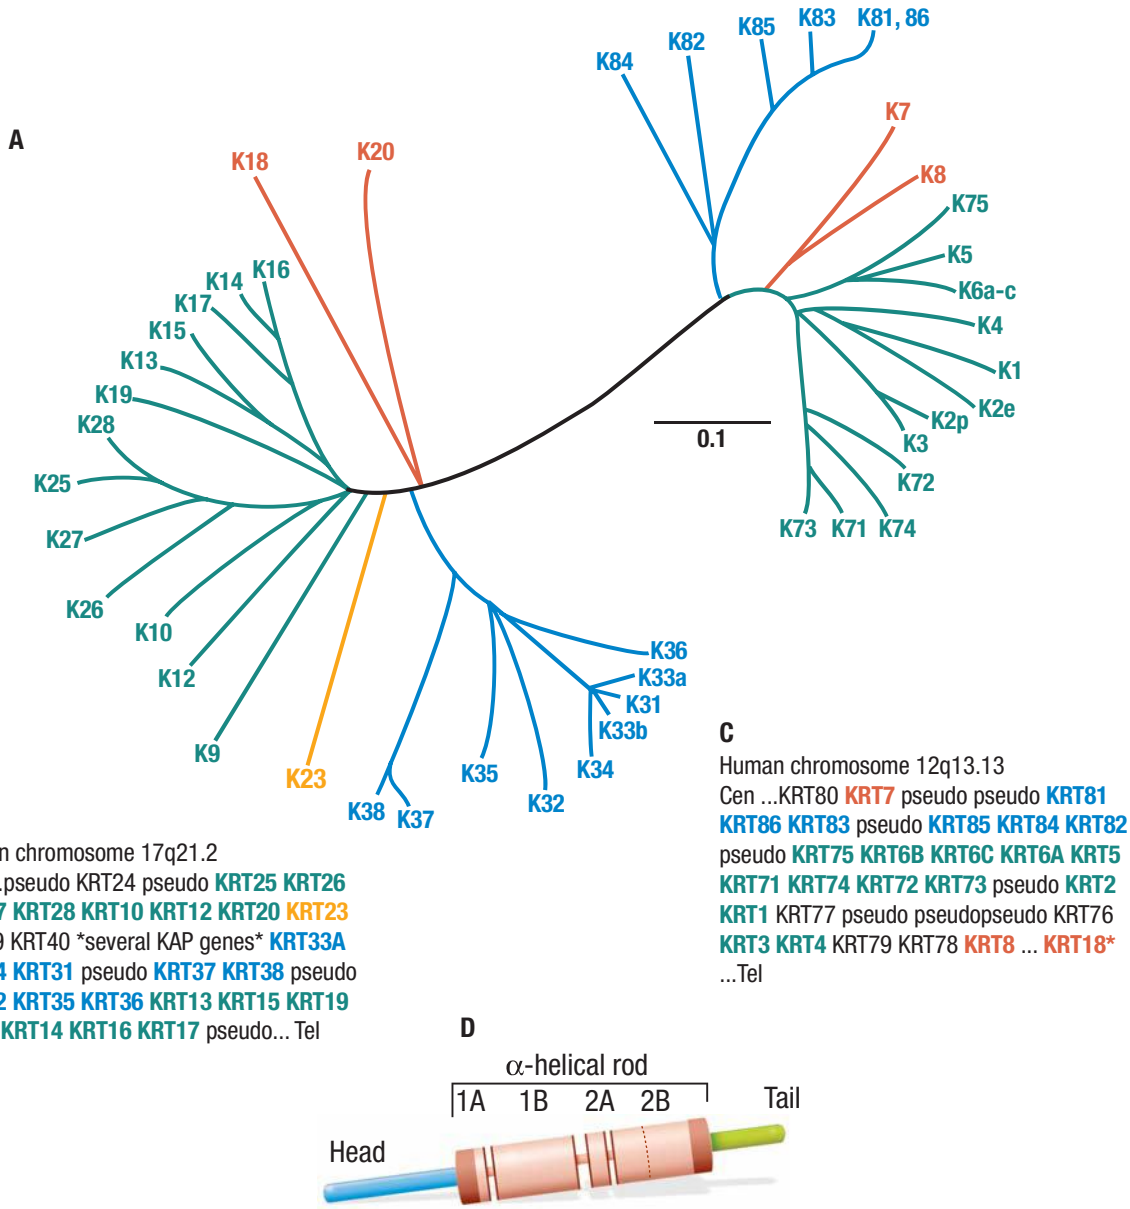
Keratins and Their Classification

Keratins (also known as *cytokeratins*) are structural proteins that belong to the superfamily of intermediate filament (IF) proteins. They are heterogeneous in size (40 to 70 kd) and charge (isoelectric point, 4.7 to 8.4), and notoriously insoluble. Sequencing the human genome revealed the presence of 54 functional keratin genes that are nearly perfectly conserved in many other mammals.[65] The tremendous diversity of keratin genes had not been fully appreciated until the advent of database mining and genomics and could not be accommodated in the original nomenclature system aptly devised by Roland Moll, Werner Franke, and colleagues in 1982.[66] An international effort recently yielded a revised nomenclature (Table 44-1) that accommodates the newly discovered keratins, adheres to the guidelines of the Human and Mouse Gene Organization Gene Nomenclature Committee, and maintains the designation of keratins originally devised by Moll and colleagues.[65]

Sequence homology and gene substructure (number and position of introns) reveal two distinct groups of keratins of roughly equal size, designated types I and II IF genes (Fig. 44-3A).[65,67] In *Homo sapiens*, functional type I and type II keratin genes are clustered on the long arms of chromosomes 17 (see Fig. 44-3B) and 12 (see Fig. 44-3C), respectively.[65,68] Keratin genes are highly conserved across mammals, at the level of their organization, structure, sequence, and regulation.[69] Mature filaments contain types I and II keratins in a 1:1 molar ratio.[67,70] This requirement underlies the coordinated transcription of types I and II keratin genes. Remarkably, most types I and II keratin genes are regulated in a pair wise, tissue type–, and differentiation-related fashion.[71–73] This is illustrated particularly well in stratified epithelia such as epidermis (Fig. 44-4). Given their large number, differential regulation, and ease of detection (owing to abundance), keratin messenger RNAs and proteins represent unparalleled markers for staging the fate and differentiation of epithelial cells, under healthy and diseased conditions.

Keratin Proteins Form the Intermediate Filament Network of Epithelial Cells

Despite sequence differences, all keratins display the tripartite domain structure



▲ **FIGURE 44-3** The human keratin gene family. **A.** Comparison of the primary structure of human keratins using the publicly available ClustalW and TreeView software. Sequence relatedness is inversely correlated with the length of the lines connecting the various sequences, and to the number and position of branch points. This comparison makes use of the sequences from the head and central rod domain for each keratin. A few keratins were left out for clarity purposes. Two major branches are seen in this tree display, corresponding to type I and type II sequences. Beyond this dichotomy, each subtype is further segregated into major subgroupings (denoted by different colors). **B.** Organization of functional type I keratin genes, all of which are clustered on human chromosome 17, with the only exception being K18 (see *asterisk* in **C**), which is located at the telomeric (Tel) boundary of the type II gene cluster. A large number of genes encoding keratin-associated proteins (KAPs) interrupts the type I gene cluster, between KRT40 and KRT33A. **C.** Organization of functional type II keratin genes, which are clustered on human chromosome 12. The K8 and K18 genes are separated by 450,000 base pairs. **D.** Schematic representation of the tripartite domain structure shared by all keratin and other intermediate filament proteins. A central α-helical "rod" domain acts as the major determinant of self-assembly. This rod domain is partitioned into subdomains 1A, 1B, 2A, and 2B, and flanked by non-helical "head" and "tail" domains at the N- and C-termini, respectively. Both ends of the rod domain contain 15 to 20 amino-acid regions (*red*) that are highly conserved among all intermediate filament proteins. Cen = centromere; pseudo = pseudogene (non-functional). (Adapted from Coulombe PA, Bernot K: Keratins and the skin, in *Encyclopedia of Biological Chemistry*, Vol. 2, Elsevier Inc., 2004, with permission.)

that is typical of IF-forming proteins (see Fig. 44-3D). The central domain consists of an extended α helix featuring long-range heptad repeats that mediate coiled-coil dimerization. This "rod" domain is approximately 310 amino acids long and is flanked by highly variable sequences at the N-terminal head and C-terminal tail domains (see Fig. 44-3D).[67] Neither terminal domain exhibits known motifs other than the glycine loops seen in epidermal keratins.[74] The head and tail domains are readily protease accessible at the surface of the filament, where they can foster interactions with neighboring filaments, other proteins, or serve as substrates for post-translational modifications involved in their regulation.[68] Given their heterogeneity of size and primary structure, the head and tail domains are expected to make key contributions to the differential function and regulation of keratin proteins in vivo.[75]

The central rod domain of keratins is the main determinant of self-assembly, with important contributions from the head domain as well.[76] The ex-

traordinary stability of keratin subunits reflects the tightness of interactions between type I and type II keratins.[77] Most of the intracellular pool of keratin proteins (> 95 percent) is polymerized.[68] There is evidence that keratin IF assembly begins at the cell periphery, near the cortical F-actin cytoskeleton, in cultured epithelial cells.[78]

Keratins form the major IF network in almost all epithelial cells.[66,67,73] The abundance and organization of keratin IFs in vivo differ among epithelia. Keratin proteins are highly abundant (10 percent to 80 percent of total cellular proteins) in surface-exposed stratified squamous epithelia (e.g., epidermis, oral mucosa, corneal epithelium, etc.).[71] In epithelial cells of such tissues, keratin IFs are organized in a pan-cytoplasmic network extending from the surface of the nucleus to the cytoplasmic periphery, where they are membrane-anchored at sites of cell-matrix and cell-cell adhesion (hemidesmosomes, desmosomes) (Fig. 44-4B). In simple epithelia (e.g., liver, gut, pancreas, etc.), keratins are less abundant. In such tissues, polarized epithelial cells often feature asymmetrically organized keratin IFs concentrated mostly at the cytoplasmic periphery and, particularly, the apical pole.[68] Several associated proteins contribute to the organization and regulation of keratin IFs in these various settings.[79] Some of these proteins promote the bundling of keratin IFs (e.g., filaggrin, trichohyalin), and their association with microtubules and microfilaments (e.g., plectin, BPAG isoforms) and/or with desmosomes or hemidesmosomes (desmoplakin, plakophilin, BPAG isoforms, etc.) (see Fig. 44-4). Other partners, e.g., TRADD, 14-3-3, Akt, reflect the newly discovered participation of keratin IFs in signaling roles.[80]

Keratin Gene Expression Mirrors Epithelial Differentiation: The Case of Epidermis

Skin provides a beautiful example of the tight relationship that has evolved between keratin gene regulation and epithelial differentiation. More than one-half of all known keratin genes are expressed in mature mammalian skin tissue alone. The architectural complexity of adult skin epithelia is achieved through a temporally and spatially regulated expression of keratin and a number of other epithelial differentiation-related genes.[71,81] In the clinical setting, keratin typing is often exploited in diagnosing cancer type, its differentiation status (and therefore prognosis), as well as the origin of the cells forming metastatic foci. This strategy is also applied for diseases other than cancer.[68]

In "thin" interfollicular epidermis (e.g., trunk; see Fig. 44-4), mitotically active cells of the basal layer act as progenitors, and consistently express K5 and K14 as their main keratin pair, along with lower levels of K15. Onset of differentiation coincides with the appearance of the K1/K10 pair through a robust transcriptional induction that occurs at the expense of the K5/K14 genes, which are downregulated.[71,81] Accordingly, K1/K10 keratins are readily detectable in the lowermost suprabasal layer of epidermis (see Fig. 44-4D). The appearance of K1 and K10 correlates with a sudden and dramatic shift in the organization of keratin IFs, which now exhibit significant bundling.[82] Another type II gene, K2, is expressed at a later stage of differentiation (i.e., the granular layer).[83]

The epidermis of palm and sole skin is specialized for resisting a high degree of mechanical stress, and thus is markedly thicker. This function is reflected in its architecture of alternating stripes of primary and secondary ridges,[14] and again, in keratin expression. In the thick, stress-bearing, primary ridges, the major differentiation-specific (type I) K9 is presumed to foster a more resilient cytoskeleton. In the thinner secondary ridges, postmitotic keratinocytes preferentially express the (type II) K6a and (type I) K16 and K17.[84] Relative to K1, K9, and K10, the properties of K6a, K16, and K17 likely foster greater cellular pliability, thereby providing flexible "hinge" regions between the more rigid,

K1/K9-rich primary ridges.[84] Although this attractive model remains to be supported by direct experimentation, it is consistent with the dramatic upregulation of K6a, K6b, K16, and K17 that occurs in keratinocytes recruited from wound margins to participate in the restoration of the epidermal barrier after injury.[80,85]

Function of Keratin in the Epidermis and Other Skin Epithelia

A major function fulfilled by keratins and all other IF proteins is to enhance the cell's ability to withstand trauma. This structural support function[67,68] is made possible by the unique mechanical properties exhibited by IF networks.[80] This function is enhanced by attachment of IFs to adhesion complexes (desmosomes, hemidesmosomes) and to F-actin and microtubules.[67,68,79] Partial or complete loss of this function, e.g., through inherited mutations, underlies a wide variety of rare diseases that render cells fragile and unable to sustain mechanical stress (see Chap. 60). In vivo, the mechanical properties of IF networks likely need to be modulated, in a dynamic fashion, to meet the demands placed on cells by changing physiological circumstances. To a degree, varying needs along a continuum of viscoelastic properties likely account for the dynamic regulation of keratin IF genes and their proteins in vivo.[80]

The recent discovery of nonmechanical functions for keratin proteins has placed the field on an exciting new path.[80] In hair follicles, K17 promotes the anagen (growth) phase by attenuating TNF-α–induced apoptosis in matrix keratinocytes.[90] In the epidermis, the suprabasally expressed K10 regulates proliferation in the basal layer of epidermis and in sebaceous glands, likely through a non–cell-autonomous mechanism,[91,92] whereas K17 cell-autonomously regulates protein synthesis and cell size in wound-proximal keratinocytes.[93] Keratins influence the melanin pigment distribution and, thus, skin pigmentation.[94–96] In polarized epithelia, keratin IFs impact the distribution of organelles, routing of specific outer membrane proteins, and response to stress.[97] These newly defined keratin functions, which are just beginning to be understood, involve regulated interactions between keratin proteins and non-cytoskeletal proteins, many exerting key roles in specific signaling pathway.[79,80,97] Interference with these functions could play a role in the pathogenesis of disorders linked to IF gene mutations.[68] The discovery of these novel keratin functions provides an opportunity to better understand the diversity and context-dependent regulation of IF genes and their proteins.

Mutations in Epidermal Keratins Underlie Several Inherited Skin Blistering Diseases (See Chap. 60)

The following general principles can be drawn from the large body of data accumulated to date while studying keratin-based disorders (see Chaps. 47, 48, and 60). The majority of cases involve single missense mutations acting in a dominant-negative fashion. Small insertions and deletions are also seen with some frequency.[110] In this setting, dominance implies that disease-causing mutant keratin proteins do not markedly alter the early stages of assembly (dimer, tetramer formation) up to the step(s) involving subunit incorporation in a growing IF polymer.[68] Depending on their nature and location within the keratin protein backbone, these mutations exert a wide range of effects on the assembly or organization of IFs in keratinocytes, with a corresponding impact on the severity of clinical presentation.

CORNIFIED ENVELOPE

Alongside the substantial buildup in keratin IFs inside keratinocytes, two specializations allow the epidermis to build a remarkably effective and mechanically resilient barrier: the CE, a covalently cross-linked protein polymer that forms underneath the plasma membrane, and an extracellular hydrophobic phase that is made up of specialized lipids synthesized by terminally differentiating keratinocytes.[116] Epidermal lipids are discussed in detail in Chap. 45.

The CE represents a complex assembly of covalently cross-linked proteins that forms underneath, and eventually replaces, the keratinocyte membrane in the granular layer of epidermis, as part of the final push to complete terminal differentiation. This 20-nm thick sheath, which is so insoluble and stable it resists extended boiling in the presence of strong denaturants, encased the cell's interior and significantly contributes to the physicochemical properties of the stratum corneum compartment.[117] The extraordinary stability of the CE results in large part from the large number of ε-(γ-glutamyl)-lysine isopeptide bonds between its primary constituents, which are further reinforced by disulfide bridges. These isopeptide bonds are catalyzed by transglutaminases, a family of calcium-dependent enzymes.[118] The outer aspect of the CE is covalently linked to ceramides and other specialized lipids that are produced by, and secreted from, differentiated granular keratinocytes, whereas large bundles of tightly packed keratin IFs are cross-linked to its inner aspect.

The major protein constituents of the CE are loricrin, involucrin, filaggrin, elafin, cystatin A, cornifelin, several small-proline rich proteins and calcium-binding S-100 proteins, and "late-envelope proteins." In addition to these proteins, key components of desmosomes (e.g., desmoplakin, envoplakin, and periplakin) and several type II keratins (K1, K2, K5) are also cross-linked into the CE (Table 44-2).[117–119] CE proteins have several interesting features in common. First, many CE proteins are encoded by genes clustered as part of the epidermal differentiation complex locus on human chromosome 1q21. In addition to obvious evolutionary implications, this genomic clustering brings up the distinct possibility of coordinated regulation through cis-acting determinants.[116,119] Second, many of these proteins are made as precursors that are activated by proteolytic cleavage, calcium binding, or other modifications at the time of CE formation. Third, many CE proteins are made of repeated units that lack an intrinsically defined three-dimensional structure. Fourth, virtually all CE proteins are transglutaminase substrates.[116,118]

Involucrin, loricrin, and filaggrin, in particular, are well characterized components of the CE.[117,118] Involucrin biosynthesis is initiated in the spinous compartment, soon after the onset of K1/K10 keratin expression, in differentiating epidermal keratinocytes. It is the first major component to be activated and cross-linked into the emerging CE, possibly reflecting a scaffolding role, and is concentrated on the outermost aspect of the mature CE. Profilaggrin and loricrin are synthesized in precursor forms and stored in keratohyalin granules. Loricrin is the major structural component of the CE (approximately 80 percent by weight)—this largely unstructured but highly flexible protein features glycine loops as described for type II keratins. Once activated via dephosphorylation and proteolytic cleavage, filaggrin participates in the bundling of keratin IFs in the late granular compartment of epidermis (hence accounting for its incorporation into the CE) and also is degraded to free amino acids that contribute to the cornified cell's ability to re-

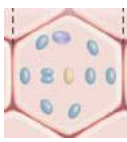

TABLE 44-2
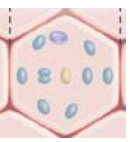
Protein Composition of the Cornified Envelope

Protein	Molecular Weight (kD) (Precursor Form)	Chromosome Location	Cornified Envelope (CE) Percent Contribution	Comments/Disease Association
Loricrin	26	1q21	80	Rich in Gly, Ser, Cys residues; contains glycine loops; flexible; stored in keratohyalin granules; mutated in Vohwinkel syndrome, a mutilating keratoderma with ichthyosis, and in progressive symmetric erythrokeratodermia, a related condition.
Involucrin	65	1q21	5	Made up of repeated units; highly α-helical; Gly-, Asp-rich; early TG substrate; may act as a scaffold during CE assembly.
Small proline-rich proteins	6–18	1q21	3–5	Encoded by 15 genes that are differentially regulated in various stratified epithelia. Great transglutaminase substrates; influence CE's mechanical properties.
Cystatin A	12	3cen-q21	2–5	Cysteine protease inhibitor; also stored in keratohyalin granules; mutations in cystatin M/E cause harlequin ichthyosis.
Late CE proteins	9–12	1q21	Unknown	Encoded by 18 genes; synthesized and incorporated at a late stage of CE formation.
Profilaggrin/ filaggrin	> 400; 36	1q21	< 1	Also bundles keratin filaments; degraded to single amino acids, which markedly contribute to retain water, in stratum corneum layers; mutated in ichthyosis vulgaris, a mild but very common condition; risk factor in individuals with atopic dermatitis and asthma.
S-100A	10–14	1q21	< 1	Family of EF-hand-containing, calcium-binding proteins; believed to transmit calcium-dependent signals.
Proelafin	10	20q12-q13	< 1	Elafin is the active entity and acts as a serine protease inhibitor.
Annexin 1	36	9q12-q21	< 1	Also known as *lipocortin*; interacts with S-100A11.
Keratins (K1, K2, K5, K10, K14)	56–70	12q13	< 1	Type II keratins are transglutaminase substrates; keratin intermediate filaments become covalently linked to the inner aspect of the CE.
Desmosomal proteins	195–330	Various	< 1	Includes desmoplakin, envoplakin, periplakin, and others. Assembly of CE is initiated at desmosome cell–cell contacts.

Note: A review article by Eckert RL et al: Transglutaminase function in epidermis. *J Invest Dermatol* **124**:481, 2005, served as a direct inspiration for this table.



tain water. Basic information about other CE components is provided in Table 44-2.[117,118] The protein composition and fine structure of the epidermal CE differs to a degree from those of the other stratified squamous epithelia; the underlying significance of this CE heterogeneity is unclear.[117,118] The important contribution of the CE towards proper barrier function in epidermis is reflected in the clinical symptoms associated with mutations altering their primary constituents in the context of human diseases (see Table 44-2).[116]

CONCLUDING REMARKS

In this chapter, we have discussed the concept of stem cells, which play key roles in the epidermis, hair follicles, and all other self-renewing tissues. Although follicular epithelial stem cells can give rise to TA cells that participate in epidermal repair, the epidermis seems to have its own stem cell population distinct from that of the follicle. We also discussed the changes of keratins during epidermal differentiation. It is well appreciated that specific type I and type II keratins are co-expressed as pairs associated with various stages of normal and pathologic epidermal differentiation, and that mutations of major epidermal keratins cause various forms of skin blistering diseases; however, the functional implications of these different keratins, not only in terms of structural roles, but also in terms of their novel involvements in signal transduction and organelle transport, is just beginning to be understood. Additional studies are needed to better understand the roles of stem and TA cells in epidermal proliferation and homeostasis; how the niche microenvironment maintains epidermal stem cells; the detailed relationship between epidermal and hair follicular epithelial stem cells and their relative contributions to skin diseases such as psoriasis and skin neoplasms such as basal and squamous cell carcinoma; and how the keratin filaments function, at the atomic level, in normal and diseased epidermis. These future studies should lead to new modalities, including cell and gene therapies, for a better treatment of some of the devastating skin diseases.

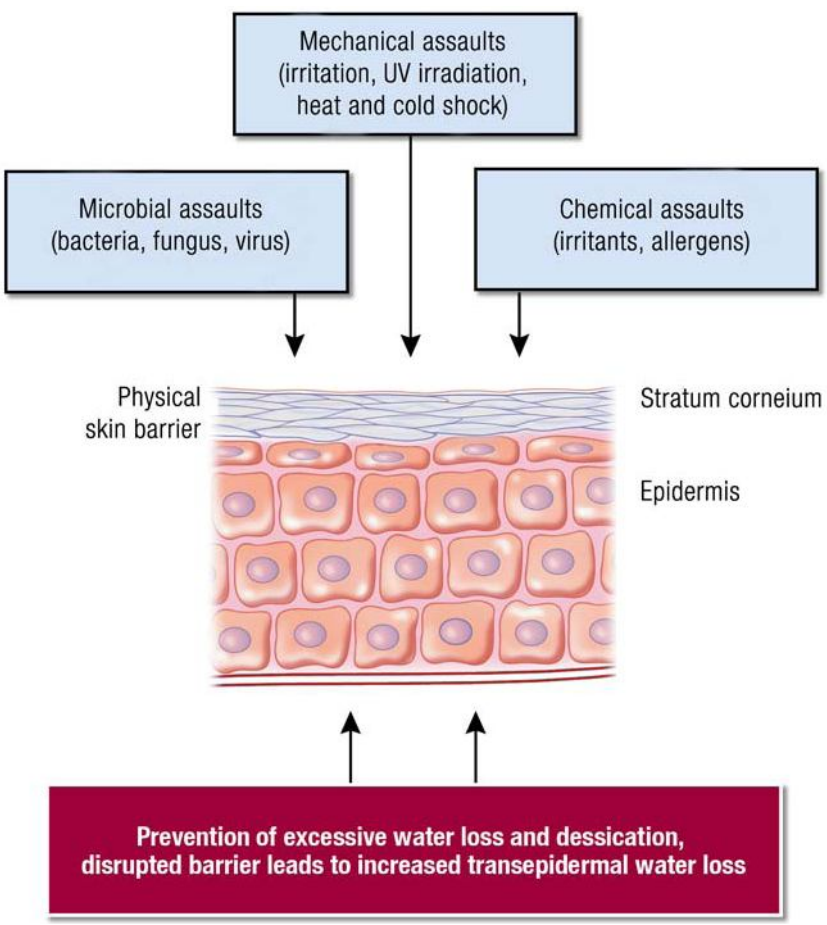
CHAPTER 45

Skin as an Organ of Protection

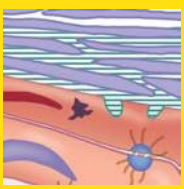
Ehrhardt Proksch
Jens-Michael Jensen

The skin's most important function is to form an effective barrier between the "inside" and the "outside" of the organism. Life on dry land requires the presence of a barrier to regulate water loss and prevent desiccation, commonly referred to as the *inside-outside barrier*. The skin also provides an *outside-inside barrier* to protect against mechanical, chemical, and microbial assaults from the external environment (Fig. 45-1). To perform these functions, the epidermis undergoes keratinization, a process in which epidermal cells progressively mature from basal cells with proliferative potential to the lifeless, flattened squames of the stratum corneum (SC) (Fig. 45-2). Both the SC and the deeper skin layers protect the skin from ultraviolet (UV) radiation, mechanical forces, and cold and hot temperatures. To effectively perform this multiplicity of functions, the skin contains different types of barriers. The physical barrier consists mainly of the SC, but the nucleated

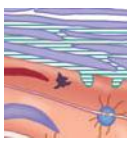


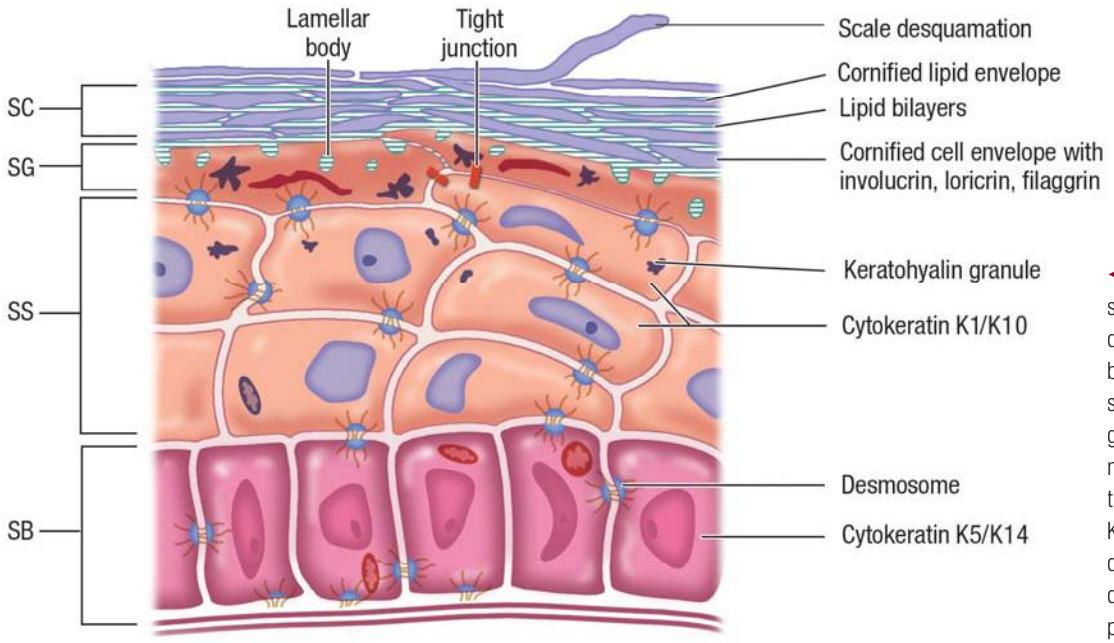
▲ **FIGURE 45-1** Functions of the epidermal "inside-outside" and "outside-inside" barrier. UV = ultraviolet.

SKIN BARRIER AT A GLANCE



- The most important function of the skin is to form a barrier between the organism and the environment.
- The skin barrier prevents excessive water loss (inside-outside barrier) and the entry of harmful substances from the environment (outside-inside barrier).
- The physical barrier is predominantly located in the stratum corneum.
- The stratum corneum barrier is composed of corneocytes and intercellular lipids, cholesterol, free fatty acids, and ceramides.
- Keratins and cornified envelope proteins are important for the mechanical stability of the corneocytes.
- The cornified envelope protein involucrin binds ceramides covalently, forming a backbone for the subsequent attachment of free ceramides.
- The nucleated epidermis through tight junctions and desmosomes also contributes to the barrier.
- Experimental barrier disruption increases epidermal lipids and changes in epidermal differentiation.
- The signals for barrier recovery are cytokines and the calcium ion gradient.
- Several diseases are characterized by a probably genetically disturbed barrier function. The disturbed barrier function contributes to disease pathology, in particular in contact dermatitis, atopic dermatitis, forms of ichthyosis, and psoriasis.
- Lipid or lipid-like creams and ointments can repair disturbed barrier function.





◀ **FIGURE 45-2** Progressive maturation of the epidermis from the stratum basale (SB), via the stratum spinosum (SS) and stratum granulosum (SG) to the terminal differentiated layer, the stratum corneum (SC). Key molecules of the epidermal structure are derived during the differentiation process.

epidermis, in particular the tight junctions, provides another important barrier component. The chemical-biochemical (antimicrobial) barrier consists of lipids, acids, lysozymes, and antimicrobial peptides. The humoral and cellular immune system provides a barrier to infectious disease (see Chap. 10), but immune hyperactivity may lead to allergy (Table 45-1).

Although the skin is of central importance for preventing water loss in a dry environment, aquatic animals also require a skin barrier to protect them from the high salinity of their surrounding environment. Terrestrial mammals with dense fur have much thinner skin than animals without this protective coat, demonstrating that fur itself is a considerable barrier. The relatively hairless skin of pigs shows much similarity to human skin and is therefore a good model for skin research.

In addition to the SC, the entire skin, as a whole, serves a protective function. The innermost region of human skin, the subcutaneous fat layer, offers mechanical shock protection, insulates the body against external heat and cold, and is active in general energy metabolism and storage. The dermis is composed of collagen bundles and elastic fibers and is very important for the mechanical strength of the skin. The epidermis, the skin's outer layer, consisting primarily of stratified nucleated keratinocytes and the SC, is most important for skin protection and the focus of this chapter. Sweat glands and blood vessels regulate body temperature. Sebaceous glands secrete sebaceous lipids to protect the hair from the environmental stress. In animals, sebaceous lipids serve as a water repellent for the fur, aiding in buoyancy and temperature regulation, and also preventing desiccation of the body and UV damage. The role of sebaceous lipids for SC barrier function and for dry skin is still a matter of discussion.[1] Sebaceous glands also transport glycerol to the skin surface, which is important for SC hydration.[2] Nerve fibers are chemosensitive and act as a warning system against external trauma.

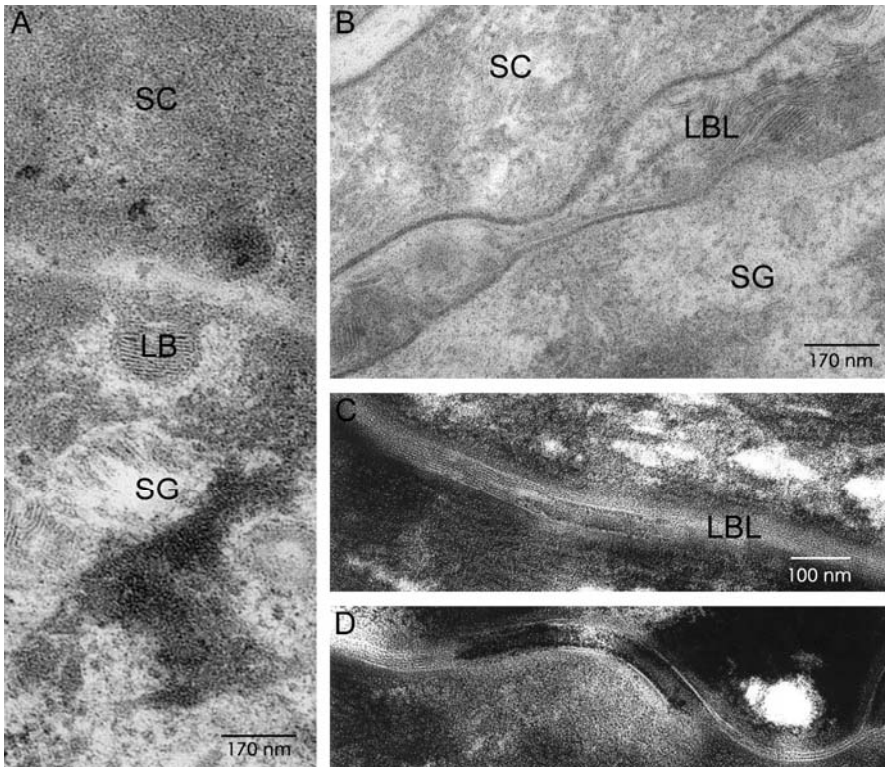
STRUCTURE OF THE STRATUM CORNEUM: PHYSICAL PERMEABILITY BARRIER

The SC is the specific location of the physical barrier.[3,4] The typical basket-weave appearance of the SC in routine formalin-embedded sections does not give the impression that it could function as an effective barrier. With the advent of electron microscopy and ruthenium tetroxide fixation, the structure of the SC barrier can now be visualized (Fig. 45-3). The barrier regulating water permeation is not absolute. The normal movement of water from the SC into the atmosphere is known as *trans-epidermal water loss* (TEWL). The SC also serves as the principal barrier against the percutaneous penetration of chemical substances and microbial assaults and is capable of withstanding mechanical forces.[5]

The 10 to 20 μm thick SC forms a continuous sheet of protein-enriched cells, embedded in an intercellular matrix, enriched in nonpolar lipids, and organized as lamellar lipid layers. The viable epidermis is a stratified squamous epithelium, consisting of basal, spinous, and granular cell layers. Each layer is defined by its position, shape, morphology, and the differentiation status of its keratinocytes. On leaving the basal layer, keratinocytes begin to differentiate and undergo a number of changes in both structure and composition during the apical migration into the stratum spinosum and stratum granulosum. Keratinocytes synthesize and express numerous structural proteins and lipids during their maturation. The final steps in keratinocyte differentiation are associated with profound changes in their structure, resulting in their transformation into flat and anucleated squamous cells of the SC, acting mainly with keratin filaments and surrounded by a cell envelope composed of cross-linked proteins (cornified envelope proteins) as well as a covalently bound lipid envelope (see Fig. 45-2). Extracellular nonpolar lipids surround the corneocytes to form a hydro-

TABLE 45-1
Different Skin Barriers

Physical barrier	Stratum corneum, nucleated epidermis (desmosomes, tight junctions)
Chemical/biochemical (antimicrobial) barrier (innate immunity)	Lipids, organic acids, lysozymes, antimicrobial peptides
Immune barrier humoral and cellular immune system	Lymphocytes, neutrophils, monocytes, Langerhans cells



▲ **FIGURE 45-3** Electron microscopy revealed that in the stratum granulosum (SG)/stratum corneum (SC) interface the lamellar bodies (LB) content is extruded to the interface (**A**), thus forming continuous lipid bilayers (LBL) (**B** then **C**). Desmosomes are becoming corneosomes in the process of cornification (**D**).

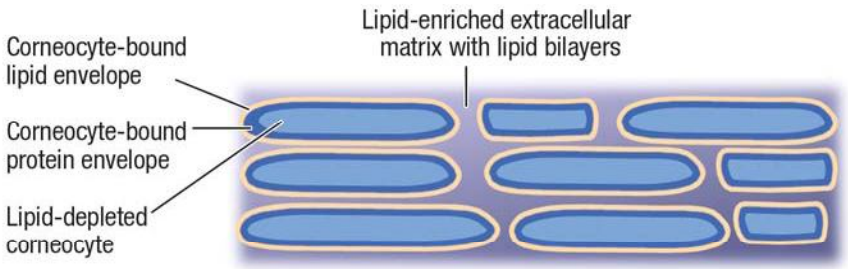
phobic matrix. The cornified envelope proteins as well as the covalently bound lipid envelope are thought to be important for the chemical resistance of the corneocytes (Fig. 45-4). Desmosomes, which interconnect adjacent keratinocytes, are important for SC cohesion and are shed during the desquamation process in the SC. In the upper spinous and granular layers, characteristic lamellar vesicles appear, which are called *epidermal lamellar bodies* (Figs. 45-3 and 45-5). These are enriched in polar lipids, glycosphingolipids, free sterols, phospholipids, and catabolic enzymes, which deliver the lipids required for the SC's extracellular layers. The lamellar bodies may also contain proteins such as human β-defensin 2.[6] In response to certain signals, probably an increase in calcium concentration during the transition from the granular layers to the SC, the lamellar bodies move to the apex of the upper-most granular cells, fuse with the plasma membrane, and secrete their content into the intercellular spaces through exocytosis. The lipids derived from the lamellar bodies are subsequently modified and rearranged into intercellular lamellae positioned approximately parallel to the cell surface. The covalently bound lipid envelope acts as a scaffold for this process. After the extrusion of the lamellar bodies into the stratum granulosum-SC interface, the polar lipids are enzymatically converted into nonpolar products. Hydrolysis of glycosphingolipids generates ceramides while phospholipids are converted into free fatty acids. These changes in lipid composition and cell structure result in the formation of a very dense structure packed into the interstices of the SC (Table 45-2).[7]

Lipid Composition and Role of Lipids in the Stratum Corneum

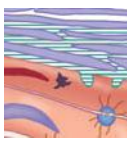
Confocal laser scanning microscopy and X-ray microanalysis studies have shown that the major route of penetration results in the tortuous halfway between the corneocytes, confirming that intercellular lipids play an irreplaceable role in regulating skin barrier function.[7] The major lipid classes in the SC are cholesterol, free fatty acids, and ceramides (Fig. 45-6).[8-10]

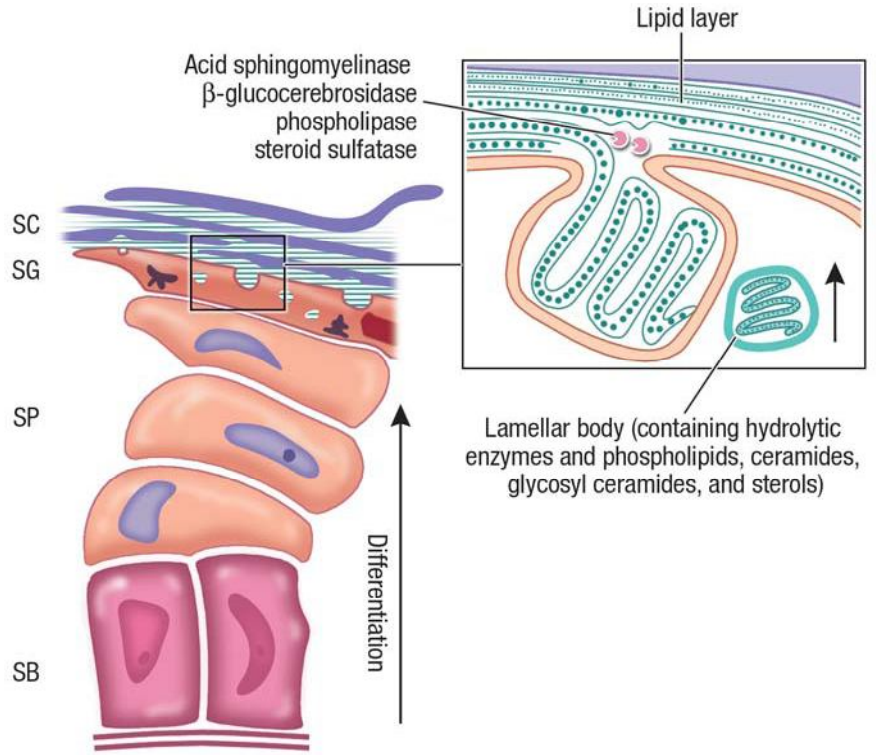
CHOLESTEROL Cholesterol is probably the most abundant lipid in the entire body and part of the plasma membrane, and part of the intercellular lipid lamellae in the SC. Although basal cells are capable of resorbing cholesterol from circulation, most cholesterol in the epidermis is synthesized in situ from acetate.[11] The epidermal keratinocyte, the main cell type in the epidermis, is highly active in the synthesis of several lipids, including cholesterol and free fatty acids. The rate-limiting step in cholesterol biosynthesis is catalyzed by hydroxymethylglutaryl CoA reductase (Fig. 45-7). Epidermal cholesterol synthesis is regulated by these enzymes and increased during permeability barrier repair.[12]

FREE FATTY ACIDS The skin contains free fatty acids as well as fatty acids bound in triglycerides, phospholipids, glycosylceramides, and ceramides. The chain length of free fatty acids in the epidermis ranges from C12 to C24. The rate-limiting enzymes acetyl-CoA carboxylase and fatty acid synthase in the epidermis are largely autonomous (Figs. 45-7 and 45-8).[13] Saturated and monounsaturated fatty acids are synthesized in the epidermis, in contrast to di- and polyunsaturated acids. The nomenclature of the fatty acids is determined from the position of the first double bond in the molecule, starting from the terminal methyl group. In particular, the essential ω-6-unsaturated acids must be obtained from food and the circulation or can be obtained by topical treatment. The non-essential monounsaturated fatty acid, the oleic acid, is an ω-9 fatty acid. The most important double unsaturated fatty acid, linoleic acid, is an ω-6 fatty acid. Also of importance is α-linoleic acid (ω-3). No skin changes due to an ω-3 fatty acid deficiency are currently known; however, it has been proposed that these fatty acids are important for the resolution of inflammation. ω-3 fatty acids are obtained from fish,



▲ **FIGURE 45-4** The lipid-depleted corneocyte is surrounded by an inner protein envelope and an outer lipid envelope. Special ceramides are covalently bound to cornified envelope proteins, particularly to involucrin.





▲ **FIGURE 45-5** During differentiation, the upper stratum spinosum (SP) and the stratum granulosum (SG) cells generate lamellar bodies containing preformed lipid structures and hydrolytic enzymes. Their content is extruded into the SG-stratum corneum (SC) interface and undergoes profound remodelling. SB = stratum basale.

whereas ω-6 fatty acids are obtained from plant oils.[14,15] Essential fatty acid deficiency (EFAD) caused by unusual human diets or malabsorption or experimentally induced in rats and mice leads to the EFAD syndrome, characterized by profound changes in epithelia including the epidermis.[16] In this condition, the epidermis is rough, scaly, and red and shows a severely disturbed permeability barrier function. In addition, severe bacterial infection, impaired wound healing, and alopecia may occur. Linoleic acid is part of phospholipids, glucosylceramides, ceramide 1, ceramide 4, and ceramide 9.[17] It has been proposed that the linoleic acid metabolite γ-linoleic acid is of special importance for atopic eczema.

CERAMIDES Ceramide is an amide-linked fatty acid containing a long-chain amino alcohol called *sphingoid base*. The carbon chain lengths of amide-linked fatty acids and sphingoid bases in most mammalian tissues are 16 to 26 and 18 to 20, respectively (see Fig. 45-6). Although sphingolipids, including glycosphingolipids and phosphosphingolipids, are ubiquitously distributed in mammalian tissues, tissue-specific molecular distribution has been described. Glucosylceramide is enriched in the epidermis and spleen whereas galactosylceramide is enriched in the brain but is not detected in keratinocytes. Whereas ceramide is a minor lipid component, comprising less than 10% of cholesterol or phospholipids in other mammalian tissues, ceramide is a major lipid component in the SC, accounting for 30 to 40 percent of lipids by weight. Moreover, such a high content of ceramides in the SC is not observed in the epidermal stratum granulosum, stratum spinosum, or stratum basale. This also suggests that terminal differentiation is a key factor in accumulating ceramide. The SC contains at least nine different ceramides.[17] In addition, there are two protein-bound ceramides, ceramide A and ceramide B (see Fig. 45-6).[7] These ceramides are covalently bound to cornified envelope proteins, most importantly to involucrin.

Ceramides are synthesized by serine-palmitoyl transferase as rate-limiting enzyme and by hydrolysis of both glucosylceramide (by β-glucocerebrosidase)[18] and sphingomyelin (by acid sphingomyelinase) (Figs. 45-8 and 45-9).[19] Whereas all kinds of ceramides are derived by synthesis from serine-palmitoyl transferase and from β-glucocerebrosidase, only ceramide 2 and ceramide 5 are obtained from sphingomyelinase because sphingomyelin contains nonhydroxy acids.[20]

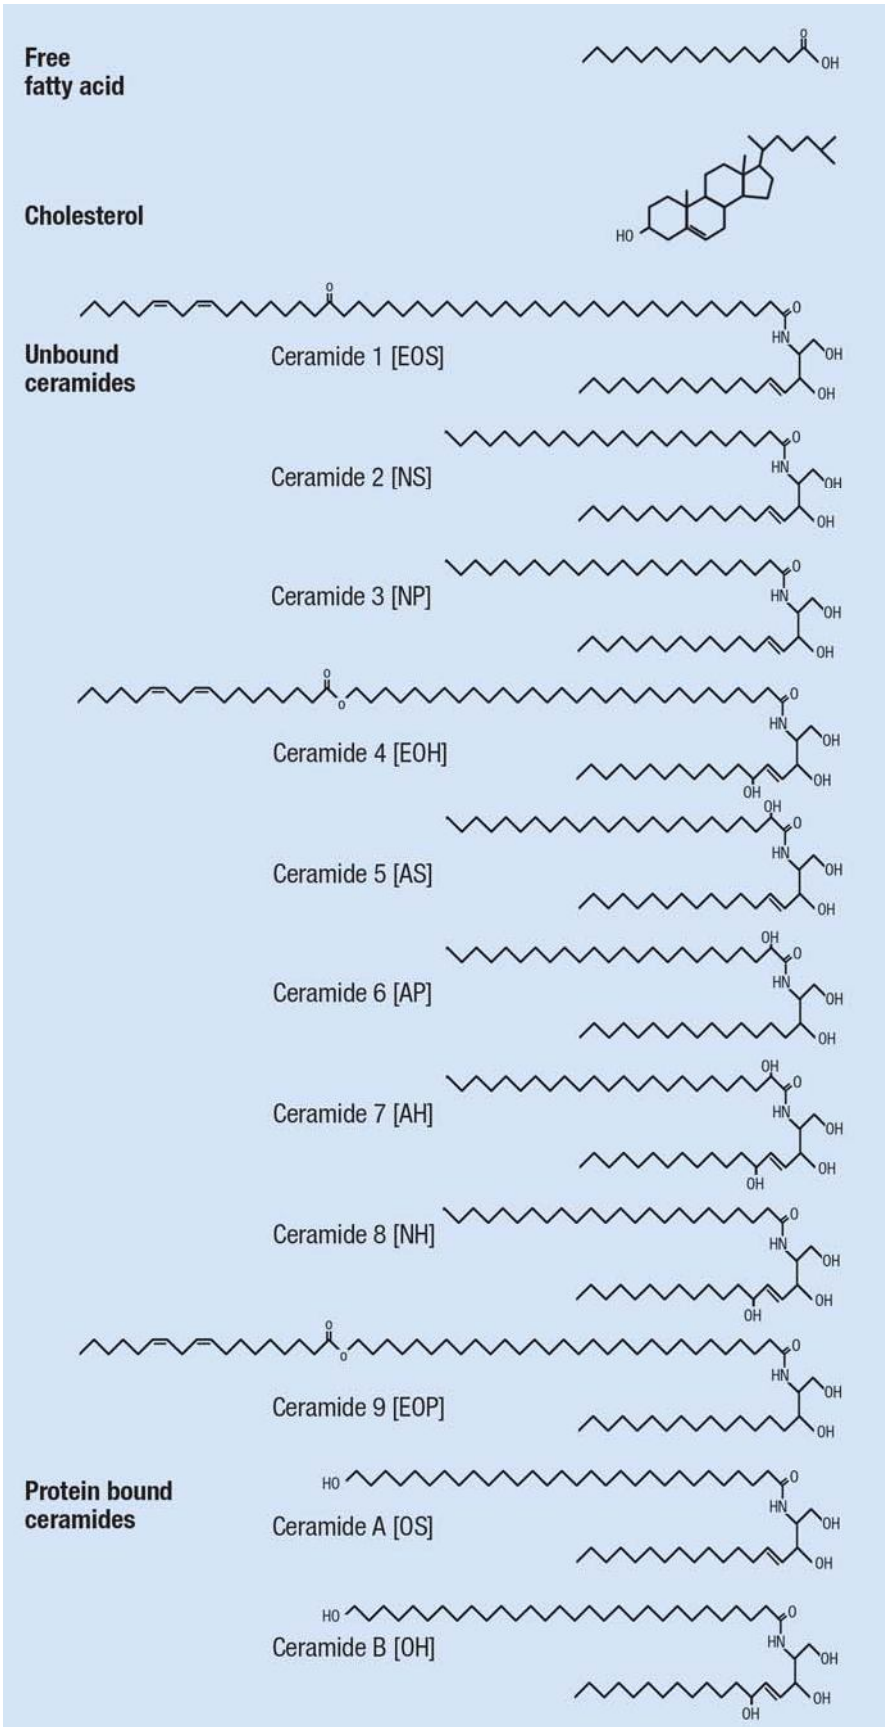
Lipid Transport

Keratinocytes require abundant cholesterol for cutaneous permeability barrier function. ABCA1 is a membrane transporter responsible for cholesterol efflux and plays a pivotal role in regulating cellular cholesterol levels. It was demonstrated that ABCA1 is expressed in cultured human keratinocytes and murine epidermis. Liver X receptor activation and activation of peroxisome proliferator-activated receptor (PPAR)-α, PPAR-ss/δ and retinoid X receptor increased ABCA1

TABLE 45-2
Protective Functions of the Stratum Corneum

Functions	Structural Bases	Biochemical Mechanisms
Permeability barrier	Lamellar bilayers	Hydrophobic lipids
Mechanical integrity/ resilience	Cornified envelope, cytosolic filaments	Cross-linked peptides (e.g., involucrin, loricrin), keratin filaments
Hydration	Lamellar bilayers; corneocyte cytosolic matrix	Sebaceous gland-derived glycerol, filaggrin break-down amino acids, natural moisturizing factors
Cohesion/desquamation	Corneodesmosomes	Serine proteases
Antimicrobial defense	Lamellar bilayers, extracellular matrix	Free fatty acids, antimicrobial peptides
UV protection	Corneocyte cytosol	Structural proteins, trans-urocanic acid
Antioxidant defense	Corneocytes, extracellular matrix	Keratins, sebaceous gland-derived vitamin E and other antioxidants
Waterproofing/repellence	Lamellar bilayers	Keratinocyte and sebum-derived lipids
Cytokine signalling	Corneocyte cytosol	Storage and release of pro-IL-α, serine proteases
Xenobiotic defense	Lamellar bilayers	Lipid solubility, cytochrome p_{450} system (outer epidermis)

IL = interleukin; UV = ultraviolet.



▲ **FIGURE 45-6** The stratum corneum lipid barrier contains free fatty acids, cholesterol, and different ceramide sub-types. Protein-bound ceramides and very-long-chain ceramides provide an anchor between the protein envelope proteins and the free intercellular lipids.

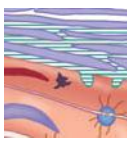
expression in keratinocyte cultures. Thus cholesterol levels for permeability barrier function are regulated by ABCA1, liver X receptor, and PPARs.[21] The cellular fatty acid transport and metabolism is regulated by fatty acid-binding proteins.[22]

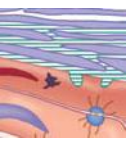
EPIDERMAL PROLIFERATION AND DIFFERENTIATION IN SKIN BARRIER FUNCTION

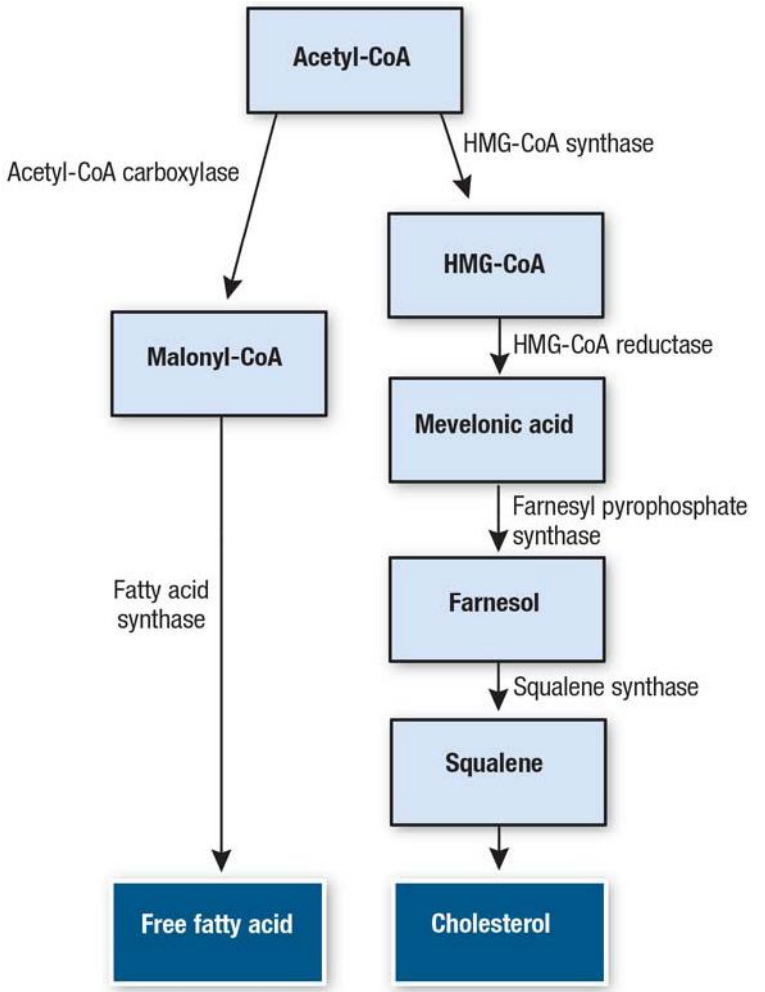
To provide this physical barrier of the SC, not only intercellular lipids, but also the corneocytes are of crucial importance.[23,24] The epidermis undergoes keratinization in which epidermal cells progressively mature from basal cells with proliferative potential to lifeless flattened squames of the SC (see Fig. 45-2). Keratinocytes arise from stem cells in the basal layers and transient amplification cells and move to a series of differentiation events until they are finally brought to desquamation.[25] Thus, in the normal epidermis, there is a balance between the processes of proliferation and desquamation that results in a complete renewal approximately every 28 days (see Chap. 6). In some of the ichthyoses, the rate of desquamation may be decreased, leading to epidermal cell retention (retention hyperkeratosis) (see Chap. 47).[26] In inflammatory skin diseases like psoriasis, there is an increase in proliferation resulting in a disturbance in differentiation and parakeratotic squames (hyperproliferative hyperkeratosis) (see Chap. 18).[27]

Keratins are major structural proteins synthesized in keratinocytes (see Chap. 44). They assemble into a web-like pattern of intermediate filaments that emanate from a perinuclear ring, extend throughout the cytoplasm, and terminate at junctional desmosomes and hemidesmosomes. During the final stages of normal differentiation, keratins are aligned into highly ordered and condensed arrays through interactions with filaggrin, a matrix protein. In keratin disorders, the filament networks collapse around the nucleus, preventing attachment with the filament-matrix complex and the inner surface of squames and alter interaction between neighboring cells, thereby affecting desquamation. Filaggrin aggregates the keratin filaments into tight bundles. This promotes the collapse of the cell into a flattened shape, which is characteristic of corneocytes in the cornified layer. Together, keratins and filaggrin constitute 80 to 90 percent of the protein mass of mammalian epidermis.[23,24]

The structural proteins involucrin, loricrin, trichohyalin, and the class of small proline-rich proteins are synthesized and







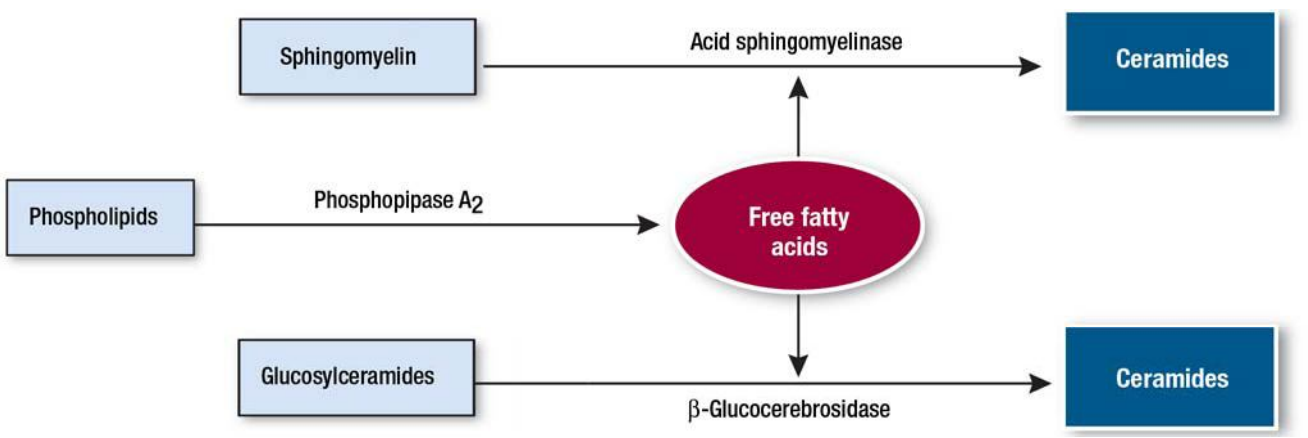
▲ **FIGURE 45-7** Synthetic pathways and key enzymes for stratum corneum free fatty acids and cholesterol. CoA = coenzyme A; HMG-CoA = hydroxymethylglutaryl CoA.

subsequently cross-linked by transglutaminases to reinforce the cornified envelope just beneath the plasma membrane. The proteins of the cornified envelope constitute approximately 7 to 10 percent of the mass of the epidermis. These corneocytes provide the bulwark of mechanical and chemical protection, and together with their intercellular lipid surroundings, confer water impermeability. The cornified cell envelope is a tough protein-lipid polymer structure formed just below the cytoplasmic membrane and subsequently resides on the exterior of the corneocytes (see Fig. 45-4). It is resistant to 10 percent potassium hydroxide and is the rigid structure seen on potassium hydroxide skin scrapings (see Chap. 188). It consists of two parts: a protein envelope and a lipid envelope. The protein envelope contributes to the biomechanical properties of the cornified envelope as a result of cross-linking of specialized cornified envelope structural proteins by both disulfide bonds and N(ε)-(γ-glutamyl)lysine isopeptide bonds formed by transglutaminases.[24,28] The isopeptide bonds are resistant to most common proteolytic enzymes. The corneocyte-bound lipid envelope is plasma membrane-like structure, which replaces the plasma membrane on the external aspect of mammalian corneocytes.[29] Involucrin, envoplakin, and periplakin serve as substrates for the covalent attachment ω-hydroxyceramides with very long chain N-acyl fatty acids of by ester linkage.[30] These not only provide a coating to the cell, but also interdigitate with the intercellular lipid lamellae (Table 45-3).[24]

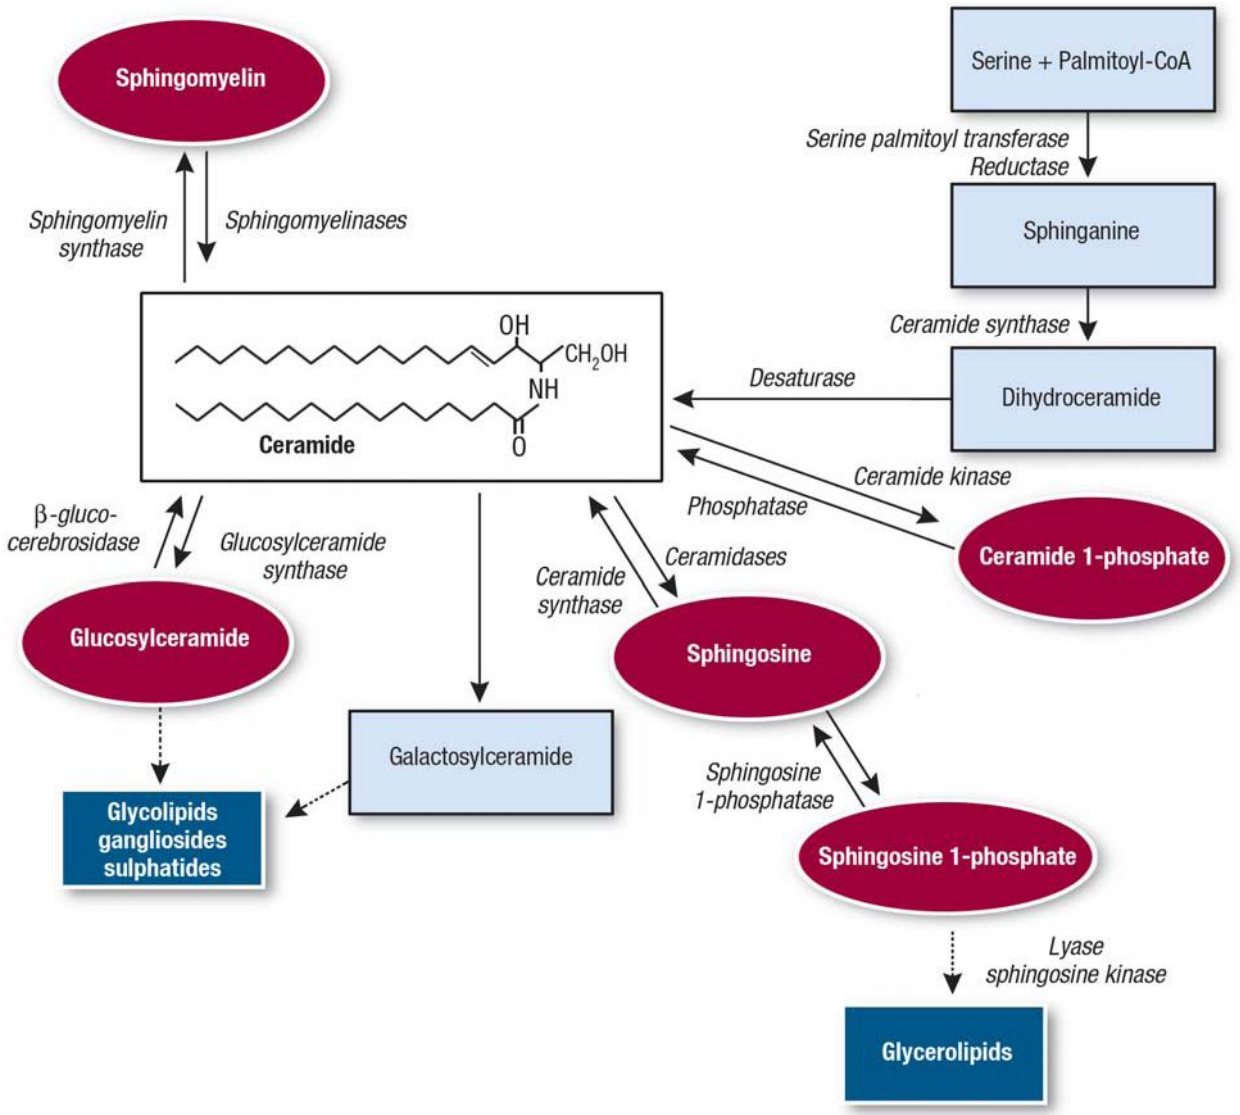
EXPERIMENTAL BARRIER DISRUPTION AND GENE MODIFICATION IN EPIDERMAL DIFFERENTIATION

Experimental barrier disruption leads to changes in epidermal keratin and cornified envelope protein expression and, vice versa, overexpression and deficiency of these proteins in mice result in barrier defects. A number of diseases displaying defective epidermal barrier function are also the result of genetic defects in the synthesis of either keratins, cornified envelope proteins, or the transglutaminase 1 cross-linking enzyme.

Inhibition of hydroxymethylglutaryl CoA reductase by topical application of the lipid lowering drug lovastatin results in a disturbed barrier function and in epidermal hyperproliferation. Therefore, the specific relationship between barrier function and epidermal DNA synthesis was examined. After acute skin barrier



▲ **FIGURE 45-8** Sphingomyelin and glycosylceramides are precursor for ceramide generation, whereas phospholipids are precursors of fatty acids.



▲ **FIGURE 45-9** Generation and degradation of ceramides.

disruption (local acetone treatment or by tape-stripping) (Fig. 45-10) and in a model of chronic barrier disruption (EFAD diet), an increase in DNA synthesis leading to epidermal hyperplasia was noticed.[31] The increase in DNA and lipid synthesis was partially prevented by occlusion.[14,31,32]

Also, the described acute or chronic barrier disruption leads to specific changes in epidermal keratin and cornified envelope protein expression (see Chap. 44). Increased expression of the basal keratins K5 and K14 and a reduction of the differentiation-related keratins K1 and K10 was noted. In addition, there was expression of the proliferation-associated keratins K6 and K16 as well as the inflammation-associated keratin K17 (Fig. 45-11).[33] The importance of keratins for skin barrier function was supported by studies in K10-deficient mice. Heterozygotes and homozygotes showed a mild or severe permeability barrier disruption, respectively. Importantly, homozygous neonatal K10-deficient mice exhibited an extremely delicate epidermis and died a few hours after birth. Heterozygous littermates showed a normal skin at birth but developed increasing hyperkeratosis as they grew up.[34] Barrier repair in heterozygous K10-deficient mice was delayed and skin hydration was impaired.[35] Changes in ceramide composition, a reduced amount of glucosylceramide and sphingomyelin, and reduced acid sphingomyelinase activity as well as increased involucrin content was also noted.[36] This shows that genetically determined changes in structural proteins lead to an impaired skin barrier function, changes in differentiation and lipid composition, but the detailed mechanisms remain to be determined.

The importance of keratins for skin barrier function is further supported by studies in diseases that are caused by monogenetic defects of these structural

TABLE 45-3
Additional Protective Functions of the Nucleated Epidermis

FUNCTIONS	BIOCHEMICAL CORRELATES
Antimicrobial systems	Antimicrobial peptides and lipids, iron-binding proteins, complement
Antioxidants	Glutathione, oxidases, catalase, cytochrome P_{450} system, vitamins C and E
Inflammatory mediators	Prostaglandins, eicosanoids, leukotrienes, histamine, cytokines

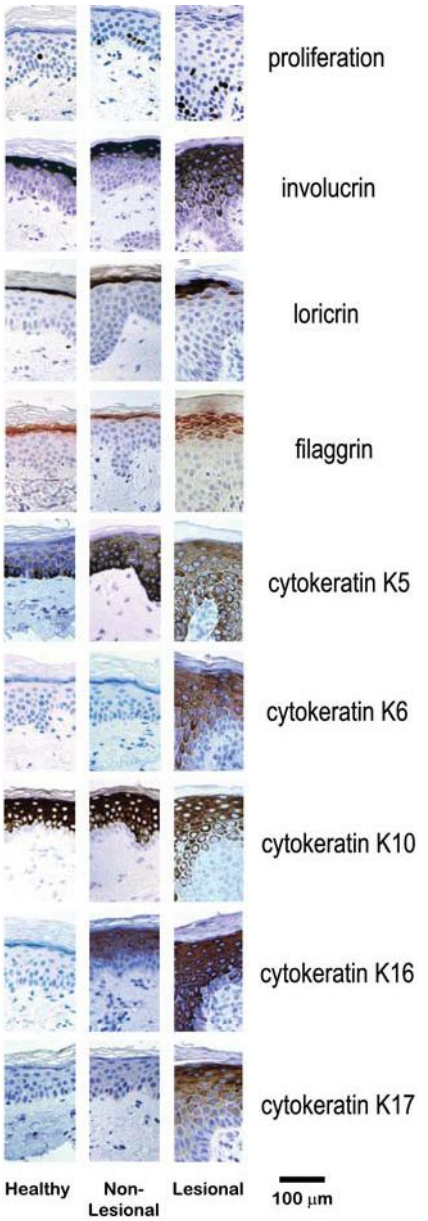
proteins. Epidermolysis bullosa simplex shows mutation in the basal layer keratins K5 or K14 (see Chap. 60). Genetic defects in the suprabasal keratins results in hyperkeratosis and a mild barrier defect (see Chaps. 47 and 48). Epidermolytic hyperkeratosis has spinous layer K1 or K10 defects, epidermolytic palmoplantar keratoderma has granular layer K9 defects (because this keratin is expressed only in palmar and plantar skin the disease is restricted to that area), and ichthyosis bullosa of Siemens has granular layer defects K2 (formerly K2e) defects (reviewed in ref. 23).

Experimental permeability barrier disruption leads to a premature expression of involucrin, but not loricrin.[33] Overexpression of filaggrin in mice in the suprabasal epidermis resulted in a delay in barrier repair.[37] Loss of normal profilaggrin and filaggrin causes flaky tail (ft/ft), an autosomal recessive mutation in mice that results in dry, flaky skin, and annular tail and paw constrictions, in the neonatal period. Targeted ablation of the murine involucrin gene did not show changes in skin barrier function under basal conditions[38] but did demonstrate a reduced ability for barrier repair. Loricrin-deficient mice did not show a disturbed barrier function, but demonstrated a greater susceptibility to mechanical stress, which may alter skin barrier function secondarily.[39,40]

Changes in epidermal proliferation and differentiation are also seen in inflammatory skin diseases with a disturbed skin barrier function (see Fig. 45-11). Increased proliferation is one of the main characteristics of psoriasis, but also in atopic dermatitis lesional skin there is a considerable increase in epidermal proliferation. Also, changes in keratins and cornified envelope proteins occur in inflammatory skin diseases.[41] Overall, this shows that there is undoubtedly a connection between epidermal proliferation, differentiation, and skin barrier function.

FUNCTIONS OF THE SUB-CORNEAL EPIDERMAL LAYERS

Although the SC is recognized as the most important physical barrier, the lower epidermal layers are also significant in barrier function. A low to moderate increase in TEWL occurs after removal of the SC by tape stripping, whereas loss of the entire epidermis through suction blisters leads to a severe disturbance in barrier function. Loss of the SC and parts of the granular layers in staphylococcal scalded-skin syndrome, are not usually life-threatening (see Chap. 178).[42] In contrast, suprabasal and sub-epidermal blistering diseases pemphigus vulgaris, toxic epidermal necrolysis (Lyell syndrome), and severe burns, respectively, are life-threatening when large areas of the body are involved (see Chaps. 39 and 94). Patients die because of extensive water loss or sepsis induced by external bacteria infection; outcomes directly resulting from perturbed barrier function. Survival rates can be greatly improved with application of an artificial barrier in the form of a foil or a grease ointment, often containing active antimicrobial substances. These clinical observations confirm the importance of the nucleated epidermal layers in skin barrier function in both directions, both in preventing excessive water loss and the entry of harmful substances into the skin.[43]



▲ **FIGURE 45-11** Skin diseases with a disturbed skin barrier function show changes in epidermal differentiation. In atopic dermatitis, these changes are already present in non-lesional and are more pronounced in lesional epidermis. The proliferation rate is significantly increased. A premature, but reduced, expression of involucrin occurs. The loricrin shows gaps in the stained band. Reduced filaggrin expression is in particular noted in non-lesional skin. Basal cytokeratin K5 expression is found in suprabasal cells in non-lesional skin and even in the entire nucleated epidermis in lesional atopic epidermis. Proliferation-associated K6 appears in lesional epidermis only. Expression of suprabasal cytokeratin K10 is found in the entire suprabasal epidermis in normal and non-lesional skin, but staining was reduced in diseased skin. K16 labelling is already found in non-lesional skin and more pronouncedly in lesional skin in atopic dermatitis, whereas inflammation-associated K17 shows immunostaining in lesional epidermis only.

Tight Junctions: A Second Line Epidermal Barrier

Tight junctions are cell junctions sealing neighboring cells and controlling the paracellular pathway of molecules, separating the apical from the basolateral parts of a cell (fence function) (see Fig. 45-2). The most important tight junction proteins in the human epidermis are occludin, claudins, and zonal occluding proteins. Localization of occludin is restricted to the stratum granulosum, zonal occluding protein-1 and claudin-4 are found in suprabasal layers, and claudins-1 and -7 are found in all epidermal layers. In various diseases with perturbed SC barrier function, such as psoriasis vulgaris, lichen planus, acute and chronic eczema, and ichthyosis vulgaris, tight junction proteins that were formerly restricted to the stratum granulosum and upper stratum spinosum were also found in deeper layers of the epidermis. Claudin-1–deficient mice die within 1 day of birth due to tremendous water loss.[44] Altered barrier function of the skin has also been demonstrated in mice overexpressing claudin-6 in the epidermis.[45,46]

Desmosomal and Adherence Junction Proteins: Structural Cell-Cell Interfaces

A perturbation in SC barrier function has also been found after the alteration of desmosomal proteins. Desmogleins are desmosomal cadherins that play a major role in stabilizing cell-cell adhesion in the living layers of the epidermis (see Fig. 45-2; see Chap. 51). Autoantibodies against these transmembrane glycoproteins cause blisters in pemphigus vulgaris due to loss of keratinocyte adhesion. In acute eczema, which shows disturbed skin barrier function, a reduction in keratinocyte membrane E-cadherin in areas of spongiosis has been found.[47,48] In transgenic mice in which the distribution of desmoglein 3 in epidermis was similar to that in mucous membrane, a highly increased TEWL resulted in lethality during the first week of life due to dehydration.[49] Mice conditionally inactivated in E-cadherin in the epidermis died perinatally due to the inability to retain a functional epidermal water barrier. Absence of E-cadherin leads to improper localization of key tight junctional proteins and in permeable tight junctions and thus altered epidermal barrier function.[50]

Connexins: Intercellular Gatekeepers

Connexins are transmembrane proteins that homo- or heteromerize on the plasma membrane to form a connexon. Connexons on adjoining cells associate to form gap junctions and allow the passage of ions and small molecules between cells. Connexin-26 is one of the most highly upregulated genes in psoriatic plaques. Missense mutations in connexin-26 result in five distinct ichthyosis-like skin disorders (see Chap. 47). In mice overexpressing connexin-26, a hyperproliferative state, infiltration of immunocells, and a delayed epidermal barrier recovery were noted.[51]

Proteases

Proteases are important for epidermal differentiation. The characteristic resistance of the cornified envelope is based on the formation of very stable isopeptide bonds that are catalyzed by transglutaminase 1, 3, and 5. Transglutaminase 1-deficient mice showed a defective SC and early neonatal death.[52] Mutations in transglutaminases 1 have been found to be the defect in lamellar ichthyosis (see Chap. 47).[53] Cathepsin D is involved in the processing of transglutaminase 1. Cathepsin D-deficient mice expressed a defect in barrier function and hyperproliferation.[54]

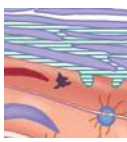
Netherton syndrome, a severe autosomal recessive genodermatosis, is caused by mutations in SPINK5, encoding the serine protease inhibitor LEKTI (see Chap. 47). In Netherton syndrome, often an atopic eczema-like skin disease with a disrupted permeability barrier is found. SPINK 5-/- mice replicate key features of Netherton syndrome, including altered desquamation, impaired keratinization, hair malformation, and a skin barrier defect. LEKTI deficiency causes abnormal desmosome cleavage in the upper granular layer through degradation of desmoglein 1 due to SC chymotryptic enzyme-like hyperactivity. This leads to defective SC adhesion and results in loss of skin barrier function.[55]

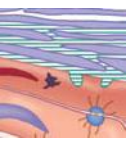
Cytokine Signaling: Regulation of Epidermal Homeostasis and Repair

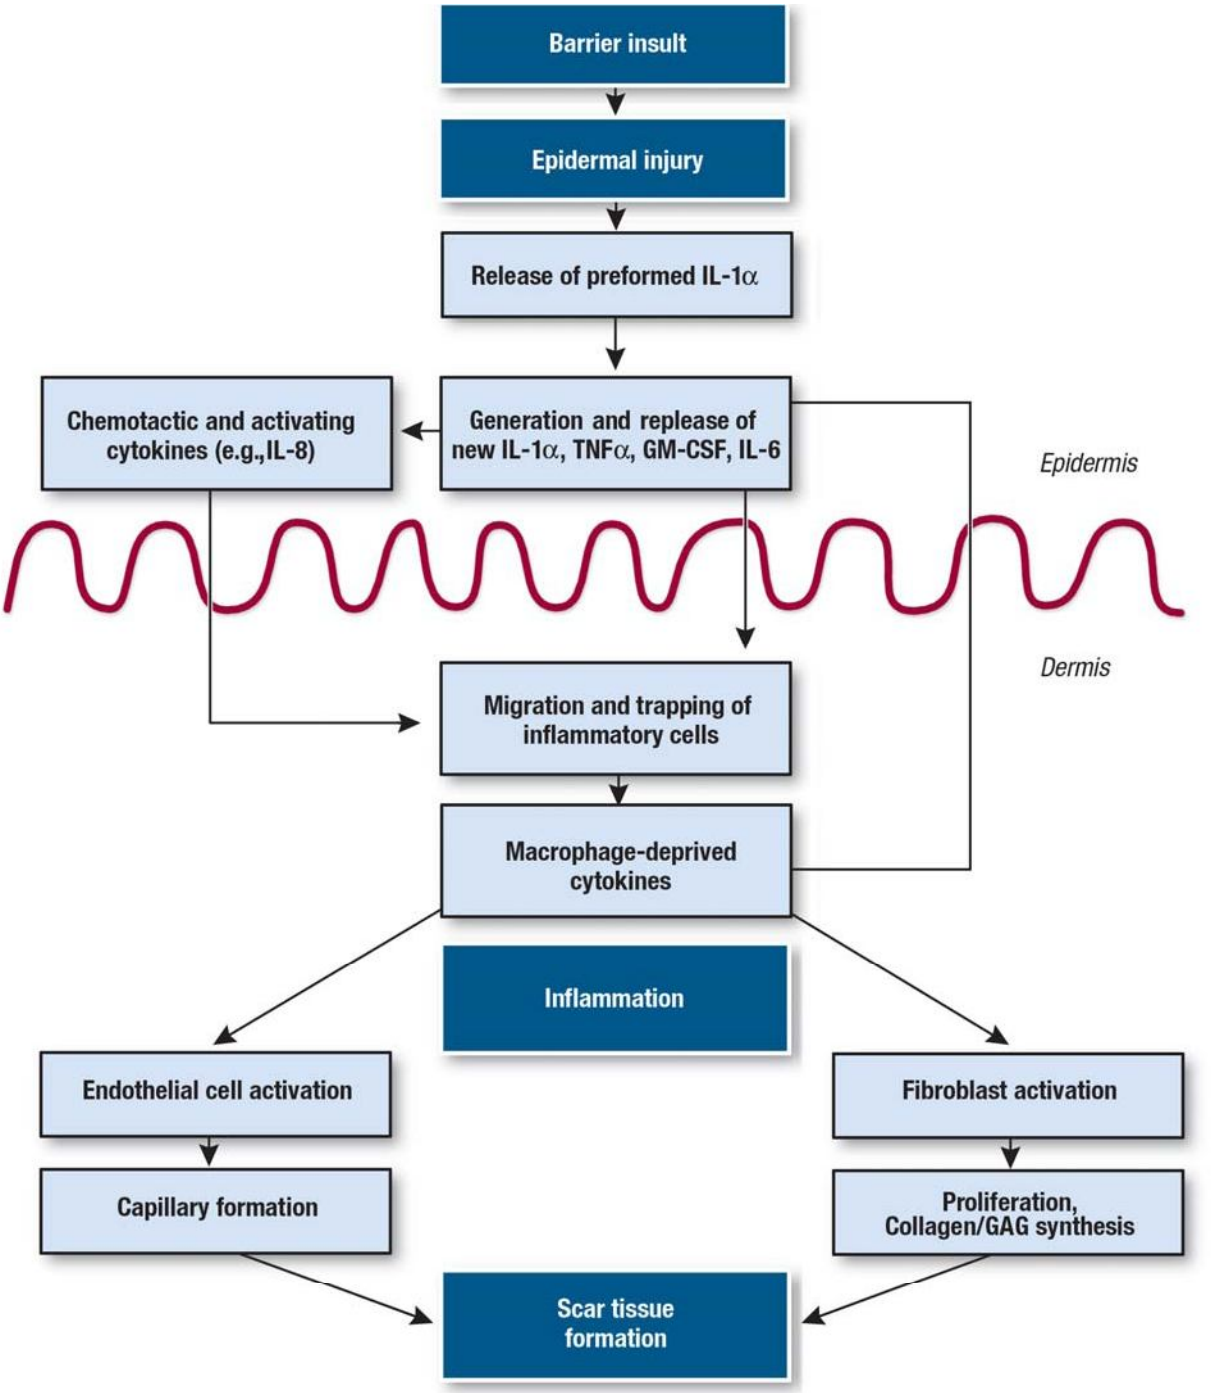
Cytokines are very important for the regulation of wound healing in which re-epithelization and differentiation to form a competent barrier is the last step (see Chap. 249). Besides the immune cells, keratinocytes are able to produce a large variety and amount of cytokines (Fig. 45-12; see Chap. 11). Of special importance are the so-called *primary* cytokines tumor necrosis factor (TNF), interleukin (IL)-1, and IL-6. The cytokines IL-1α and IL-1β are among the few that are present in the SC under basal conditions. In response to all forms of acute barrier disruption, the preformed pool of IL-1α is released.[57] IL-1, TNF, and IL-6 are potent mitogens and stimulators of lipid synthesis in cutaneous and extracutaneous tissues. After acute permeability barrier disruption an increase in the expression of TNF, IL-1, and IL-6 on the messenger RNA and the protein level occurs.[19,58,59] There is a delay in barrier repair in several genetically engineered mice, including those deficient in TNF-α receptor 1, IL-1 receptor 1 TNF-α receptor 1-double knock-out mice, and in IL-6.[19,59] Moreover, topical application of TNF enhances permeability barrier repair, and topical application of IL-6 in IL-6-deficient mice restores the normal speed in permeability barrier (see Fig. 45-12). In TNF receptor 1-deficient mice, the generation of lipids for skin barrier repair is delayed and the activity of acid sphingomyelinase, which generates ceramides for skin barrier repair, is reduced.[19] STAT3 tyrosine phosphorylation was induced after barrier disruption in wild type, but markedly reduced in IL-6-deficient mice. The acute increase in TNF, IL-1, and IL-6 after barrier disruption is crucial for skin barrier repair. However, if barrier disruption is prolonged and a chronic increase in cytokine production occurs, it could have a harmful effect leading to inflammation and epidermal proliferation. Disrupted permeability barrier, epidermal hyperproliferation, and inflammation is well known in several diseases like irritant and allergic contact dermatitis, atopic dermatitis, and psoriasis, and could aggravate the disease.

Ionic Modulations: Epidermal Calcium and Potassium Levels

A perturbed barrier recovers normally when exposed to an isotonic, hyper- or hypotonic external solution instead of air. If the solution contains both calcium and potassium the barrier recovery is inhibited. There is a calcium gradient in the epidermis with a relatively low calcium concentration in the basal epidermis, and an even lower concentration in the spinous layers, while the highest calcium concentrations are found in the granular layers. Calcium in the SC is very low because the relatively dry SC with extracellular lipids is not able to solve the high polar ions. After disruption of the permeability barrier there is influx of water into the SC and the ion gradient is lost





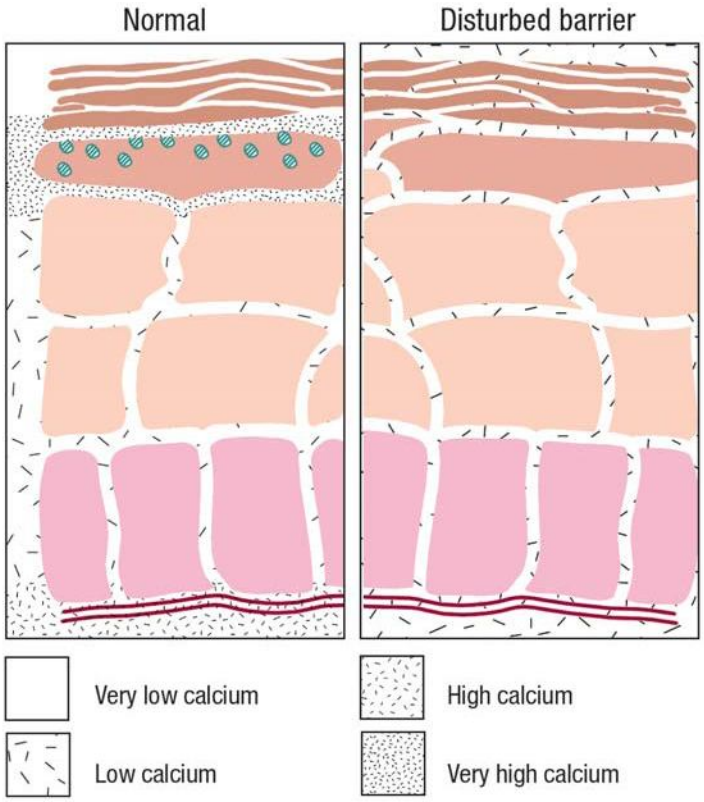


▲ **FIGURE 45-12** A barrier insult from the outside results not only in the release of cytokines for epidermal cell signaling, but also interacts with dermal processes, which may result in inflammation and ultimately scar tissue formation in case of destruction of the dermis. GAG = glycosaminoglycan; GM-CSF = granulocyte macrophage-colony stimulating factor; IL = interleukin; TNF = tumor necrosis factor.

(Fig. 45-13). This depletion of calcium regulates lamellar body exocytosis.[60-62] Calcium is a very important regulator of protein synthesis in the epidermis, including regulation of transglutaminase 1 activity.[63] Furthermore, extracellular calcium ions are important for cell to cell adhesion and epidermal differentiation. Intracellular calcium is controlled by more than one mechanism as demonstrated by two genetic diseases: Disturbed regulation of calcium metabolism and increased TEWL[64] occur in Darier disease, characterized by loss of adhesion between suprabasal epidermal cells associated with abnormal keratinization, and in Hailey-Hailey disease, which shows loss of epidermal cell to cell adhesion. The gene for Darier disease (*ATP2A2*) encodes a calcium transport adenosine triphosphatase of the sarco (endo)plasmic reticulum (SERCA2),[65,66] whereas the gene for Hailey-Hailey (*ATP2C1*) codes for a secretory pathway for calcium and manganese transport adenosine triphosphatase of the Golgi apparatus (SPCA1).[67]

Neurotransmitters in the Keratinocytes: Common Origins of the Brain and Skin

Neurotransmitters are found in keratinocytes and may regulate skin permeability barrier function. The receptors can be categorized in two groups, that is, ionotro-



▲ **FIGURE 45-13** Changes in calcium gradient after barrier disruption regulates lamellar body secretion and epidermal differentiation.

pic (calcium or chloride ion) receptors and G protein-coupled receptors. Topical application of calcium channel agonists delays the barrier recovery whereas antagonists accelerate barrier repair.

The G protein-coupled receptors modulate intracellular cyclic adenosine monophosphatase (cAMP) level, increase of intracellular cAMP in epidermal keratinocytes delays barrier recovery, whereas cAMP antagonists accelerate the barrier recovery. Activation of dopamine 2–like receptors, melatonin receptors, or serotonin receptor (type 5-HT 1) decreases intracellular cAMP and consequently accelerates barrier recovery, whereas activation of adrenergic β_2 receptors increases intracellular cAMP and delays the barrier repair. Many agonists or antagonists of neurotransmitter receptors are used clinically to treat nervous disorders. Some of them might also be effective for treating skin diseases.[68]

PATHOLOGIC SKIN BARRIERS: SKIN BARRIER FUNCTION IN DERMATOSES

A mild impairment of the skin barrier is found in monogenetic diseases expressing an impaired epidermal differentiation or lipid composition without inflammation, such as ichthyosis vulgaris, X-linked recessive ichthyosis (see Chap. 47), and Darier disease (see Chap. 49).[64] The diseases with a more pronounced barrier disruption are inflammatory diseases, such as irritant and allergic contact dermatitis (see Chaps. 211 and 13), atopic dermatitis (see Chap. 14), seborrheic dermatitis (see Chap. 22), psoriasis (see Chap. 18), and T-cell lymphoma (see Chap. 146). Also, blistering diseases, most of them inflammatory-related, show an increase in TEWL especially after loosening of the blister roof and the development of erosions (Table 45-4).

Most inflammatory skin lesions are covered with dry scales or scale-crusts due to the disturbed epidermal differentiation and an SC with poor water-holding capacity. Inflammatory skin diseases can be produced by either exogenous or endogenous causes. In contact dermatitis, disruption of the barrier by irritants and allergens is the primary event, followed by sensitization, inflammation, increased epidermal proliferation, and changes in differentiation. In T-cell lymphoma (mycosis fungoides), an endogenous cause for barrier disruption, changes in epidermal proliferation, and differentiation, by expansion of clonal malignant $CD4^+$ T cells is obvious.[69] In atopic dermatitis and in psoriasis, it is debatable whether permeability barrier disruption is followed by inflammation or whether inflammation leads to epidermal changes including barrier dysfunction. The vast majority of reports on the pathogenesis of atopic dermatitis and even more on psoriasis focused on the primary role of abnormalities in the immune system.[70] However, others have proposed an "outside-inside" pathogenesis for atopic dermatitis and other inflammatory dermatoses with barrier abnormalities,[71,72] as an alternative to the current "inside-outside" paradigm.

Atopic Dermatitis: Consequence of a Chronically Disturbed Barrier

The existence of a defective permeability barrier function in atopic dermatitis is now widely accepted. A genetically impaired skin barrier function is already present in non-lesional and more pronounced in lesional skin in atopic dermatitis. Increased epidermal proliferation and disturbed differentiation, including changes in keratins and cornified envelope proteins involucrin, loricrin, and filaggrin, and in lipid composition, cause impaired barrier function in atopic dermatitis (see Figs. 45-11 and 45-14).[73] Recently, two mutations in the filaggrin gene have been described[74] and immediately confirmed.[75,76] Two loss-of-function genetic variants in the gene encoding filaggrin are strong predispos-

TABLE 45-4

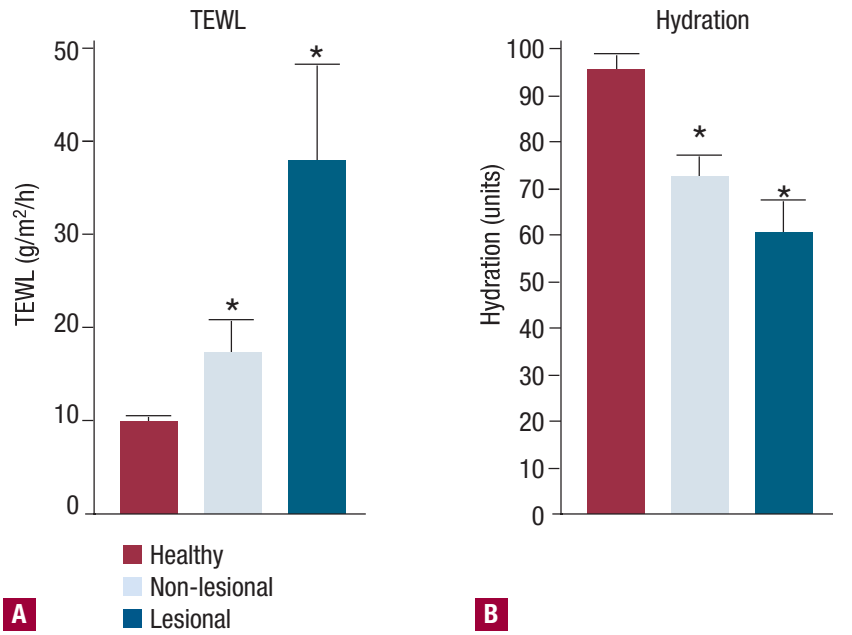
ing factors for atopic dermatitis in atopic kindreds of European origin.[77] These mutations were also significantly associated with asthma, independent of atopic dermatitis, that means that genetic factors that compromise the epidermal barrier could also underlie mucosal atopic diseases (filaggrin is a protein that is unique to keratinizing epithelia). The atopic syndrome represents a genetically impaired skin barrier function as well as impaired nasal, bronchial, and intestinal mucous membranes leading to atopic dermatitis, allergic rhinitis, bronchial asthma, or aggravation of atopic dermatitis. Defective permeability barrier function enables penetration of environmental allergens into the skin and initiates immunological reactions and inflammation (Fig. 45-15). Filaggrin mutation is the first strong genetic factor identified in this complex disease. Filaggrin hydrolysis generates amino acids in their deaminated products, which serve as endogenous humectants.[78] This may explain the dry skin well known in atopic dermatitis. Also, gene polymorphisms in the gene for SPINK5, which encodes the serine protease inhibitor LEKTI, have been reported[79] and variations within two serine proteases of the kallikrein family, the SC chymotryptic enzyme which degrades corneodesmosomal proteins, involved in the cohesion between the corneocytes of the SC, have been found in some cohorts with atopic dermatitis.

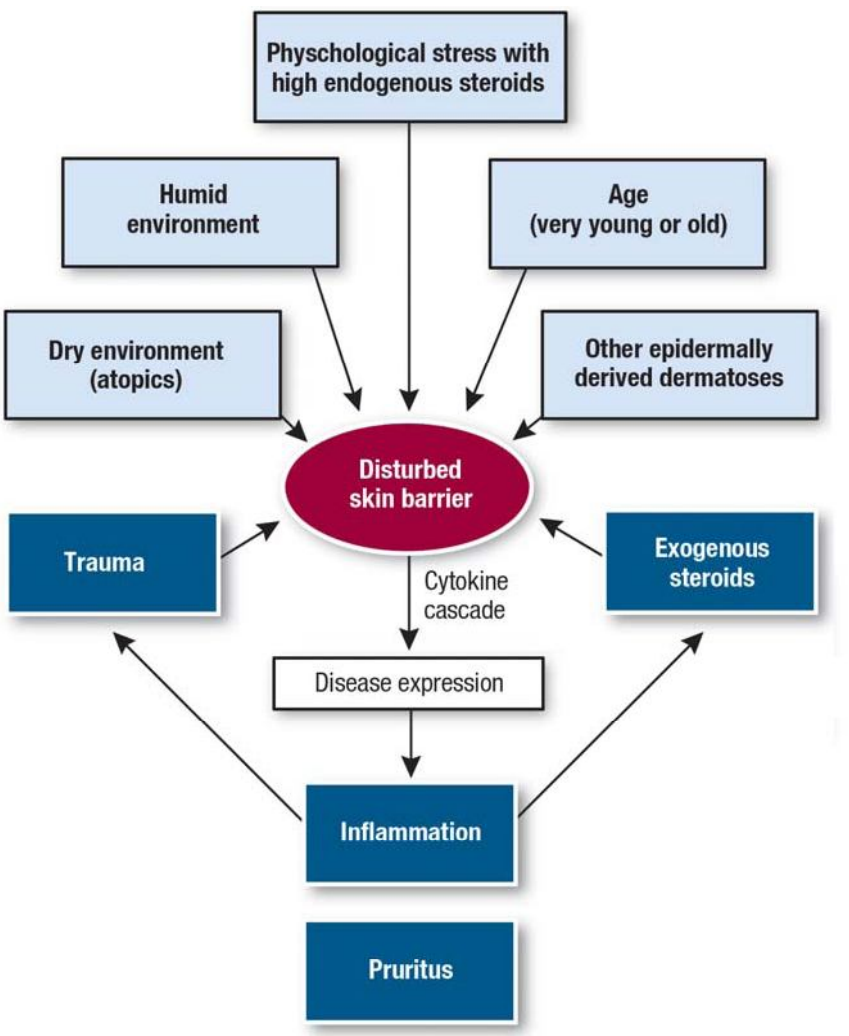
The impaired skin barrier function in atopic dermatitis is also caused by reduced lipid content or impaired lipid composition in atopic dermatitis. In particular, a decreased content for the total amount and for certain types of ceramides has been described.[72] A decrease in covalently bound ceramides[80] and a reduced sphingomyelinase activity has been found in atopic dermatitis. Also, decreased secretion of lamellar bodies, which are predominantly composed of lipids, with subsequent entombment of lamellar bodies within corneocytes, has been reported.[81]

Psoriasis: Epidermal Hyperproliferation and the Skin Barrier (See Chap. 18)

Psoriasis is a chronic, generalized, and scaly erythematous dermatosis that is primarily localized in the epidermis, showing highly enhanced proliferation and disturbed differentiation, which leads to hyperkeratosis and parakeratosis. In addition, there is a neutrophilic infiltrate in the beginning and in particular in severe cases of psoriasis; later a moderate T-lymphocytic infiltrate is present. Because of this



▲ **FIGURE 45-14** Transepidermal water loss (TEWL) (**A**) and stratum corneum hydration (**B**) are impaired in atopic dermatitis. Reduced stratum corneum hydration and enhanced TEWL are already seen in non-lesional and are more pronounced in lesional skin in atopic dermatitis.



▲ **FIGURE 45-15** Endogenous and exogenous insults lead to a disturbance in skin barrier function, thus inducing or maintaining inflammatory skin diseases in atopic dermatitis.

severely disturbed proliferation and epidermal differentiation, there is an impaired barrier function.[82] The level of TEWL is directly related to the clinical severity of the lesion: high TEWL in acute exanthematous psoriasis; a moderate increase in TEWL in the chronic plaque type of the disease. Abnormalities in the SC intercellular lipids, especially a significant reduction in ceramide 1 have been found.[83] Electron microscopy studies disclosed severe structural alteration of the intercellular lipid lamellae.[84] A genetic linkage of psoriasis to the epidermal differentiation complex 1q21 has been found. Within the epidermal differentiation complex the small proline-rich proteins are highly upregulated in psoriasis plaques.[85] Also, the association of psoriasis with cytokeratin K17 has been discussed.

Ichthyosis: Pathologic Lack of Moisture in the Epidermis (See Chap. 47)

Ichthyosis comprises a group of monogenetic diseases expressing a disturbed desquamation resulting in scales and a mild to moderate barrier defect. They are caused either by changes in epidermal lipids or by changes in epidermal differentiation. X-linked recessive ichthyosis is relative mild noncongenital ichthyosis, consisting of a generalized desquamation of large, adherent, and dark brown scales. The metabolic basis of XLRI is an enzymatic lysosomal deficiency of steroid sulfatase or arylsulfatase C. Complete deletions of the *STS* gene mapped to the Xp22.3-pter region have been found in up to 90 percent of patients. The reduced cholesterol sulfatase activity leads to accumulation of cholesterol sulfate and a reduction of cholesterol and consequent abnormality in the structural organization of the intercorneocyte lipid lamellae.[86-88]

Ichthyosis vulgaris is the most common monogenetic skin disease. Recently, loss-of-function mutations in the gene encoding filaggrin that cause ichthyosis vulgaris have been described. During terminal differentiation, profilaggrin is cleaved into multiple filaggrin peptides that aggregate keratin filaments. The resultant matrix is cross-linked to form a major component of the cornified cell envelope. Reduction of this major structural protein leads to an impaired keratinization and to a moderate defect in skin barrier function.[89]

Transglutaminase 1 is responsible for the cross-link of several cornified envelope proteins. Therefore, deficiency in transglutaminase 1[53] leads to lamellar ichthyosis, which is a more severe disease than ichthyosis vulgaris with a defect in filaggrin only.

TREATMENT IMPLICATIONS AND APPROACHES: RESTORING THE SKIN'S PROTECTIVE FUNCTION

Treatment strategies in inflammatory diseases often address immunogenic abnormalities and barrier function. Treatment with corticosteroids, cyclosporin, tacrolimus, pimecrolimus, and UV light has been shown to reduce cell inflammation as well as to improve barrier function, thus helping to normalize proliferation and differentiation. However, because of side effects, these treatments should be used for a short time only. In contrast, application of bland creams and ointments containing lipids and lipid-like substances, hydrocarbons, fatty acids, cholesterol esters, and triglycerides can be used without side effects for long-term treatment of mild to moderate inflammatory diseases. Creams and ointments partially correct or stimulate barrier repair and increase SC hydration,[41,90–92] thus influencing epidermal proliferation and differentiation.[14] It has been proposed that a lipid mixture containing the three key lipid groups (ceramides, cholesterol, and free fatty acids) is able to improve skin barrier function and SC hydration in atopic dermatitis.[93] Also, the efficacy of ceramide 3 in a nanoparticle cream in atopic dermatitis has been described.[94] However, because several research groups and companies report that creams containing ceramides and a mixture of the three key lipids are not superior to "classical" cream or ointment preparations, such preparations have not yet been widely used. More research is necessary to determine the significance of ceramides and the composition of creams and ointments with the most therapeutic benefit.

CHAPTER 46

Irritant Contact Dermatitis

Antoine Amado
James S. Taylor
Apra Sood

Dermatitis or eczema is a pattern of cutaneous inflammation that presents with erythema, vesiculation, and pruritus in its acute phase. Its chronic phase is characterized by dryness, scaling, and fissuring. Irritant contact dermatitis (ICD) is a cutaneous response to contact with an external chemical, physical, or biologic agent; endogenous factors such as skin barrier function and pre-existing dermatitis also play a role. The spectrum of presentation after contact with an irritant varies from overt dermatitis to subjective contact reaction, contact urticaria, caustic and necrotic reactions as well as pigmentary changes and other dermatoses.

EPIDEMIOLOGY

In contrast to allergic contact dermatitis (ACD), no previous exposure to the irritant is necessary in eliciting irritant reactions.[1] ICD accounts for 80 percent of all cases of contact dermatitis,[2,3] and is often occupation-related. ICD caused by personal-care products and cosmetics is also common; however, very few of these patients with these irritant reactions seek medical help because they manage by avoiding the offending agent.[4]

The incidence of ICD is difficult to determine because the accuracy of the

IRRITANT CONTACT DERMATITIS

AT A GLANCE

- Irritant contact dermatitis (ICD) is a nonimmunologic inflammation of the skin caused by contact with a chemical, physical, or biologic agent.
- Up to 80 percent of contact dermatitis is irritant and is commonly related to occupation.
- The most important exogenous factor for ICD is the inherent toxicity of the chemical for human skin.
- Endogenous factors, such as skin barrier function and pre-existing dermatitis, play an important role in the pathogenesis of ICD.
- Atopic dermatitis is a major risk factor for irritant hand dermatitis because of impaired barrier function and a lower threshold for skin irritation.
- Patch testing should be performed in cases with suspected chronic irritant dermatitis to exclude an allergic contact dermatitis.
- Identification and avoidance of the potential irritant is the mainstay of treatment.

epidemiologic data is limited. European cross-sectional studies for eczema due to all causes in the general population have shown point prevalence rates of 0.7 percent to 40 percent and 1-year to lifetime prevalence rates of 7.2 percent to 11.8 percent.[5] Data from the U.S. Bureau of Labor Statistics show that of the 249,000 cases of nonfatal occupational illnesses reported in 2004 for both genders, 15.6 percent (38,900 cases) were skin diseases, the second most frequent cause of all occupational diseases reported.[6] Based also on annual surveys of the Bureau of Labor Statistics incidence rates of occupational diseases in the American working population, contact dermatitis constitutes 90 percent to 95 percent of all occupational skin diseases, and ICD constitutes about 80 percent of occupational contact dermatitis.[7]

ETIOLOGY AND PATHOGENESIS

Four interrelated mechanisms have been associated with ICD: (1) removal of surface lipids and water-holding substances, (2) damage to cell membranes, (3) epidermal keratin denaturation,[8–11] and (4) direct cytotoxic effects.[11] There is a clearly demonstrated immunologic-like component to the irritant response,[12] which is characterized by the release of proinflammatory mediators, particularly cytokines, from nonimmune cutaneous cells (keratinocytes) in response to chemical stimuli. This is a process that does not require previous sensitization.[10] Disruption of the skin barrier leads to release of cytokines such as interleukin 1α (IL-1α), IL-1β, and tumor necrosis factor-α (TNF-α). A 10-fold increase in the levels of TNF-α and IL-6, and a threefold increase in the levels of granulocyte-macrophage colony-stimulating factor and IL-2 have been observed in ICD. TNF-α is one of the key cytokines in irritant dermatitis, leading to the increased expression of major histocompatibility complex class II and intracellular adhesion molecule 1 on keratinocytes.[10,13]

INFLUENCING FACTORS

ICD is a multifactorial disease where both exogenous (irritant and environmental) and endogenous (host) factors play a role. Occupational ICD is discussed in more detail in Chap. 211.

Exogenous Factors (Table 46-1)

Other than with strong acids and alkalis, it has not been possible to predict the irritant potential of a chemical based on molecular structure. The irritant potential of compounded formulations may be more difficult to predict. Factors to be considered include: (1) chemical properties of the irritant: pH, physical state, concentration, molecule size, amount, polarization, ionization, vehicle, solubility; (2) characteristics of exposure: amount, concentration, duration, and type of contact, simultaneous exposure to other irritants, and interval after previous exposure[4,14]; and (3) environmental factors: body region and temperature, and mechanical factors such as pressure, friction, or abrasion.[2] Low ambient humidity and cold temperature decrease the water content of the stratum corneum, making it more permeable to irritants.

When one or more irritants are combined or used simultaneously, a synergistic or antagonistic effect may occur as a consequence of specific cellular interactions between the compounds, or an alteration in the skin permeability by one or more of the compounds, that would not occur when an irritant is used alone.[4,12] This is known as the *crossover phenomenon*. In a study by Wigger-Alberti et al.,[15] concurrent application of sodium lauryl sulphate and toluene twice daily for 30 minutes to the volar forearms of healthy volunteers induced significantly stronger irritant reactions than those caused by twice-daily application of each chemical alone. This study suggests a crossover phenomenon between the two compounds by which one irritant caused an increased susceptibility to the other irritant.

TABLE 46-1
Exogenous Factors Influencing Cutaneous Irritation

- Type of irritant (pH, chemical activity)
- Cutaneous penetration of irritant
- Body temperature
- Mechanical factors (pressure, friction, abrasion)
- Environment (temperature, humidity)
- Other exposure factors: duration, prior or simultaneous exposures, direct versus airborne

Clues to causes, clinical characteristics, and control. *Postgrad Med* **103**:199, 207, 212; 1998; and Frosch PJ, John SM: Clinical aspects of irritant contact dermatitis, in *Contact Dermatitis*, 4th edition, edited by Frosh PJ, Menné T, Lepoittevin J-P. Germany, Springer-Verlag Berlin Heidelberg, 2006, p 255.

Endogenous Factors (Table 46-2)

GENETIC FACTORS It has been hypothesized that an individual's ability to quench free radicals, to change the levels of antioxidant enzymes, and the ability to form protective heat shock proteins may all be under genetic control. These factors also determine the variability in responsiveness to irritants.[16] Additionally, a genetic predisposition to irritant susceptibility may be specific for each irritant.[17]

GENDER The majority of clinical ICD affects the hands, and women account for a majority of these patients.[18] Rather than a gender-related skin susceptibility, women have more extensive exposure to irritants and wet work and are more likely to seek treatment than men.[4,14,19] No gender difference for ICD has been established experimentally.

TABLE 46-2
Endogenous Factors Influencing Cutaneous Irritation

Germany, Springer-Verlag Berlin Heidelberg, 2006, p 255.

AGE Children younger than 8 years of age are more susceptible to percutaneous absorption of chemicals and irritant reactions.[4] Most studies show no compromise in skin barrier permeation with increasing age. Data on the influence of aging on experimental skin irritation are conflicting. Visible skin irritation (erythema) is decreased in older persons while invisible skin irritation (barrier damage) might be increased in the elderly.[20]

ETHNICITY There are no studies that demonstrate that skin types significantly influence the development of ICD.[21,22] Because erythema is difficult to measure in dark skin, early studies[23] using erythema as the only parameter to quantify irritation may have led to an erroneous interpretation that black skin is more resistant to irritation than white skin. It is also possible that variations among individuals rather than ethnicity play a role in the intensity of an irritant response.[24]

SKIN SITE There are significant site differences in barrier function, making the skin of the face, neck, scrotum, and dorsal hands more susceptible to ICD. The palms and soles are comparatively more resistant.[25]

ATOPY A history of atopy is a well-known predisposing factor for irritant hand dermatitis (see Chap. 14). A history of atopic dermatitis seems to be linked to an increased susceptibility to irritant dermatitis because of a lower threshold for skin irritation, impaired skin barrier function, and slower healing process.[26]

Thus, the most important exogenous factor is the inherent toxicity of the chemical for human skin and its penetration.[27] The most important endogenous factors are atopic history and skin barrier function.[20]

TABLE 46-3
Types of Irritant Contact Dermatitis (ICD)

IRRITATION	ONSET	PROGNOSIS
Acute ICD	Acute, often single exposure	Good
Delayed acute ICD	Delayed 12–24 h or longer	Good
Irritant reaction	Acute, often multiple exposures	Good
Chronic ICD	Slowly developing (weeks to years)	Variable
Traumatic ICD	Slowly developing after preceding trauma	Variable
Acneiform ICD	Moderately slowly developing (weeks to months)	Variable
Nonerythematous (suberythematous) irritation	Slowly developing	Variable
Subjective (sensory) irritation	Acute	Excellent
Friction dermatitis	Slowly developing	Variable
Asteatotic irritant eczema	Slowly developing	Variable
Other clinical subtypes of acute and chronic ICD		
Interdigital	Slowly developing (days to weeks)	Variable
Frictional melanosis	Slowly developing (months to years)	Poor
Diaper dermatitis	Acute or delayed	Variable
Chemical burns	Acute or delayed	Variable
Nonimmunologic contact urticaria	Acute	Variable
Airborne	Acute	Variable
Scalp irritation	Acute or delayed	Variable
Nail irritation	Delayed to slow	Variable
Tandem[a]	Acute or delayed	Variable
Photoirritation[a]	Acute	Variable

CLINICAL TYPES OF IRRITANT CONTACT DERMATITIS

ICD has a spectrum of clinical features, which can be divided into several different categories, depending on the irritant and its exposure pattern.[28] But these manifestations also depend on mechanical, thermal, climatic, and constitutional factors.[14] The clinical types of ICD vary according to the irritant in question: ulceration (e.g., strong acids or alkalis), folliculitis (e.g., oils and greases), miliaria (e.g., aluminum chloride), hyperpigmentation (e.g., heavy metals), and hypopigmentation (e.g., *p*-tert-butylphenol).[10]

At least 10 clinical types of ICD have been described. They are listed in Table 46-3 along with a number of clinical sub-types of acute and chronic ICD.

1. *Irritant reaction:* An irritant reaction clinically presents as an acute monomorphic reaction that includes scaling, low-grade erythema, vesicles, or erosions and is usually localized on the dorsum of the hands and fingers. It is often seen in individuals who are exposed to wet work. An irritant reaction can resolve or progress to cumulative irritant dermatitis.[10,12]
2. *Acute ICD:* Acute ICD usually results from a single skin exposure to a strong irritant or caustic chemical, such as alkalis and acids, or as a result of a series of brief chemical or physical contacts. Most cases of acute irritant dermatitis are a consequence of accidents at work. A sensation of burning, itching, or stinging may occur immediately after the exposure to the irritant. The patient may present with erythema, edema, and vesiculation and with exudation, bullae formation, and tissue necrosis in more severe cases. The healing process of acute ICD occurs

TABLE 46-4
Airborne Irritants

- Acids and alkalis
- Ammonia
- Anhydrous calcium sulfate
- Arsenic
- Calcium silicate
- Cement
- Dichlorvos
- Domestic cleaning products
- Epoxy resins
- Formaldehyde
- Fiberglass
- Industrial solvents
- Metallic oxide powders
- Paper
- Phenol formaldehyde resins
- Sawdust from toxic trees
- Silver
- Sodium sesquicarbonate
- Urea-formaldehyde insulating foam, dust foam
- Wool dust (in atopic patients)

Clues to causes, clinical characteristics, and control. *Postgrad Med* **103**:199, 207, 212; 1998; and Frosch PJ, John SM: Clinical aspects of irritant contact dermatitis, in *Contact Dermatitis*, 4th edition, edited by Frosh PJ, Menné T, Lepoittevin J-P. Germany, Springer-Verlag Berlin Heidelberg, 2006, p 255.

as a decrescendo phenomenon, where the irritant reaction quickly peaks and then immediately begins to heal upon removal of the irritant. Complete healing may take 4 weeks, with a good prognosis.[4,12,14]

Other forms of acute irritant reaction have been also described (see Table 46-3), such as airborne contact dermatitis resulting from exposure to irritant fumes or dusts (Table 46-4).[4,14] Irritant cheilitis may result from lip licking or use of cosmetics and medication. Diaper dermatitis and perianal dermatitis may be the result of prolonged or too frequent contact with urine or fecal residues.[14] Dermatitis resulting from sodium azide released by airbag deployment has also been described,[29] causing an alkaline chemical burn; the accompanying talc powder may also contribute to the dermatitis.

3. *Delayed acute irritancy:* The delayed irritant reaction is acute but without visible signs of inflammation appearing until 8 to 24 hours or more after exposure. Otherwise, the clinical appearance and course are similar to those of an acute ICD.[4,12] The delayed presentation may simulate that of an ACD, sometimes making differentiation of the two disorders difficult, even with patch testing. Substances causing delayed irritancy are listed in Table 46-5. Delayed acute irritancy in general has a good prognosis.[10,12,14]
4. *Chronic cumulative ICD:* This is the most frequent type of contact dermatitis encountered in clinical practice. Also called *traumiterative ICD*, cumulative ICD develops as a result of repeated insults to the skin, where the chemicals involved are often multiple and weak and would not in themselves be strong enough to cause irritant dermatitis.[10,12,14] The most common marginal irritants include soap, detergents, surfactants, organic solvents, and oils,[2] which may also act as perpetuating factors once the dermatitis has become established. Cosmetic cumulative ICD is not infrequent in women, particularly in the eyelids.[14]

   Initially, cumulative contact dermatitis can appear with itch, pain, and a few localized patches of dry skin; then erythema, hyperkeratosis, and fissuring can develop.[2,4,12,14] The symptoms do not immediately follow exposure to the irritant, appearing after days, months, or years of exposure. With extensive and frequent exposure to some irritants, the skin becomes hardened, with better resistance to future irritant exposures. Hardened skin appears coarse and lichenified, which may contribute to further resistance. However, even brief periods away from exposure lower the resistance, and with re-exposure, patients are once again at risk for irritation. Chronic cumulative ICD can be confused with ACD because of the delayed and variable presentation, and appropriate diagnostic patch testing is indicated to exclude ACD. The prognosis of cumulative ICD is variable.[4,12]
5. *Subjective (symptomatic, sensory) irritancy:* Patients complain of itching, tingling, stinging, burning, or smarting sensation within minutes of contact with an irritant, but without visible cutaneous changes.[12,28] Subjective irritancy usually occurs on the face, head, and neck. Cosmetics, sunscreens, and woolen garments are commonly implicated.[3,4,28] Other common sensory irritants include lactic acid (a model for this phenomenon), propylene glycol, and aluminum salts. Stimulation of cutaneous type C nociceptors has been implicated in this form of irritancy,[12] although recently changes in cutaneous vasculature have been implicated. Some sensory irritation may be nonimmunologic contact urticaria. Screening raw ingredients or final formulations with the guinea pig ear swelling test or the human forehead assay may allow one to minimize sub-clinical contact urticaria.[30]
6. *Nonerythematous (suberythematous) irritation:* This is a state in which the irritation is not visually apparent, but is histologically visible. Common symptoms include burning, itching, or stinging. Sub-erythematous irritation has been linked with the use of consumer products containing significant amounts of surfactant.[4,12]
7. *Frictional dermatitis:* Mechanical irritation can result from repeated microtrauma and friction. Nipple dermatitis in patients with ill-fitting bras, and dermatitis from prosthetic limbs, mechanical injury from thorns and spines in plants, adhesive tape, or from handling coarse paper, glass, and rock wool fiber are only some.[10,14] This type of contact irritation usually leads to dry, hyperkeratotic abraded skin, making it more vulnerable to the effects of irritants.[4]
8. *Traumatic reactions:* Traumatic reactions can develop after acute skin trauma as

burns or lacerations and most commonly occurs on the hands and persists for about 6 weeks or longer. The healing process in this type of dermatitis is prolonged, and erythema, scaling, papules, or vesicles can appear. The clinical course can resemble that of nummular dermatitis.[4,12]

9. *Pustular or acneiform reactions:* Pustular or acneiform reactions are usually seen after occupational exposures to oils, tars, heavy metals, and halogens but also after the use of some cosmetics. The pustular lesions are sterile and transient and may develop several days after exposure. This type of dermatitis is seen especially among atopic and seborrheic patients.[4,9,12]
10. *Exsiccation eczematid:* Exsiccation eczematid usually occurs in elderly patients who frequently shower without reapplying moisturizers to their skin. Intense itching, dry skin, and ichthyosiform scaling are clinical features that characterize this irritant reaction.[12]

COMMON IRRITANTS (Table 46-6)

Water is a hypotonic element that acts as a cytotoxic agent on eroded skin.[14] Hard water has been found to be more irritating than soft water.[31] Skin cleansers cause irritation depending on the chemistry of their constituents. They remove surface lipid film, denature proteins, and damage the cell membrane. Soaps, detergents, and waterless cleansers are the most common irritants. Preservatives, especially quaternary ammonium compounds, have an irritant effect. Foods, such as citrus peels, garlic, flour, and spices, can act as irritants.[14] Capsaicin produces hand irritation after handling hot peppers and is also present in some personal defense sprays used by police or by civilians.[1] Pineapple juice contains bromelain, an irritating proteolytic enzyme.[32]

Other potential irritants include: Animal products from seafood and meat, from caterpillars, carpet beetles, and moths; topical medicaments, such as occlusive transdermal drug delivery systems, gentian violet, tar, potassium permanganate, mercury, hexachlorophene, etc.[14]; cosmetics, especially when applied to the eyelids; and alkalis, present in soap, bleaches, detergents, oven cleansers, and toilet bowl cleaners.[1] Fiberglass dermatitis can develop from wearing clothes that have been washed together with fiberglass-contaminated work clothes or with fiberglass curtains.[33] Other tear gases, [e.g., 2-chlorobenzylidene malononitrile, known as *CS* (pepper spray) and, rarely, 1-chloroacetophenone, known as *CN* (Mace)] are present in a variety of self-defense or riot-control sprays[1] and cause lacrimation, sternutation, and, occasionally, cutaneous irritation and sensitization.

TABLE 46-6
Causes of Irritant Contact Dermatitis

DIAGNOSIS

Differential Diagnosis (Boxes 46-1 and 46-2)

ICD is often diagnosed by excluding other causes for the dermatitis, including ACD.[2] A detailed inquiry, including occupational, recreational (hobbies), and past medical histories, and a meticulous clinical examination are important for making the correct diagnosis. History of exposure to friction, wet work, soaps, and detergents or exposure to organic or alkaline solvents; and/or an environmental relative humidity of less than 35 percent are key factors that support a diagnosis of irritancy.[34] When an allergic component is considered, diagnostic patch testing should be performed.[26] A biopsy often cannot differentiate allergic, irritant, or atopic dermatitis, but may be helpful in excluding psoriasis, in the case of palmar involvement. Measuring trans-epidermal water loss (TEWL) can indicate barrier impairment but cannot distinguish between ACD and ICD. Rietschel [11] has proposed criteria with subjective and objective features, each with major and minor findings for the diagnosis of ICD. The more features identified, the stronger the case for ICD (Table 46-7).

In their review of pre-market predictive tests for irritants, Basketter and Kimber[35] conclude that except where appropriate human tests, such as the 4-hour prophetic patch test, can be conducted, skin irritation tests, especially in animals, are of only limited value in the characterization of the potential effects associated with actual exposure of humans to irritants. In the clinical setting there is likely to be exposure to multiple irritants.

Box 46-1
Differential Diagnosis of Irritant Contact Dermatitis (Major Types)

Most Likely

Localized
- Seborrheic dermatitis
- Stasis dermatitis

TABLE 46-7
Diagnostic Criteria of Irritant Contact Dermatitis

MAJOR	MINOR
Subjective	
• Onset of symptoms within minutes to hours of exposure	• Onset of dermatitis within 2 wk of exposure
• Pain, burning, stinging, or discomfort exceeding itching early in the clinical course	• Many people in the environment affected similarly
Objective	
• Macular erythema, hyperkeratosis, or fissuring predominating over vesiculation	• Sharp circumspection of the dermatitis
• Glazed, parched, or scalded appearance of the epidermis	• Evidence of gravitational influence, such as dripping effect
• Healing process begins promptly on withdrawal of exposure to the offending agent	• Lack of tendency of the dermatitis to spread
• Patch testing is negative	• Morphologic changes suggesting small concentration differences or contact time produce large differences in skin damage

Adapted from Rietschel RL: Clues to an accurate diagnosis of contact dermatitis. *Dermatol Ther* **17**:224, 2004.

In attempts to predict individual susceptibility to irritants, a number of tests have been studied, including alkali resistance with sodium hydroxide, ammonium hydroxide, dimethyl sulfoxide, threshold response to various irritants (sodium lauryl sulfate, nonanoic acid, benzalkonium chloride, kerosene, croton oil, and anthralin), lactic acid stinging, minimal erythema dose with ultraviolet B (UVB), and measurement of TEWL. In their review, Frosch and John[27] conclude that none is so simple and reliable that it can be used on a large scale. A number of these procedures have been used experimentally, usually with individual chemicals, with the results having limited applicability, but they may be of some value in predicting thresholds of irritation. Of the bioengineering methods used, TEWL measurement is the most frequently used procedure to quantify impaired functions of the stratum corneum. Clinically invisible subtle damage, such as by detergents, can be reliably detected by an increase in TEWL.

Patch Testing

Patch testing is often essential to help distinguish ACD from ICD or to diagnose concomitant ICD and ACD. Negative patch tests may favor a diagnosis of ICD "by exclusion" of ACD. A diagnosis of ACD may be missed with false-negative patch test results (see Chaps. 13 and 211).[11,26] Conversely, patch testing with obvious irritants, or non-standard chemicals or mixtures can lead to false-positive patch test results. Irritant patch test reactions may present as erythema with or without papules and often remain confined to the test site and are sharply demarcated. These irritant reactions also show a decrescendo pattern, in which a decreasing severity is seen, although this is not always a reliable indicator.[3,26] Irritant patch test reactions do not equate with ICD but only reflect the irritating patch test concentration or procedure. It is important to perform comprehensive patch testing with the appropriate substances and concentrations to prevent incorrect conclusions.[11]

TREATMENT

Identification and elimination of the irritants and protection from further exposure are important in the management of ICD.[4] Once dermatitis develops, use of topical treatment is helpful. The role of topical corticosteroids in the management of ICD is controversial, but they may be helpful because of their anti-inflammatory effect.[4,36] Prolonged use of topical corticosteroids may lead to epidermal atrophy and increased susceptibility to irritants. Emollients or occlusive dressings may improve barrier repair in dry, lichenified skin.[4,14] Traditional petrolatum-based emollients are accessible, inexpensive, and have been shown to be as effective as emollient containing skin-related lipids.[37] Other "barrier creams" are of limited value.[38] Topical calcineurin inhibitors (e.g., pimecrolimus) may be used as an alternative to low-potency topical corticosteroids in chronic ICD.[39]

In severe or chronic cases, phototherapy (psoralens with UVA or UVB) or systemic drugs, such as azathioprine and cyclosporine, may be effective.[14,36] Grenz radiotherapy is a potential third-line adjunctive treatment. Bacterial superinfection can be treated with topical or systemic antibiotics.[14] In sensory irritation, strontium salts act by selectively blocking the activation of cutaneous type C nociceptors.[12]

PREVENTION

ICD is a risk factor for the development of ACD because the impaired skin barrier may increase the potential for the induction and elicitation of ACD. Thus, the prevention of irritant dermatitis means simultaneous prevention of ACD.[10,40]

Although behavior patterns that have become a matter of routine for years[40] may be difficult to change, once an irritant

has been identified as the causal factor, patients should be educated about irritant avoidance, including everyday practices that may cause or contribute to the ICD.

The use of personal protective equipment, especially in high-risk jobs, is very important. Protective gloves should be worn for any wet work. However, patients should avoid wearing waterproof gloves for long periods of time to help reduce sweating. In this case, gloves should have a fabric lining or alternatively, thin cotton gloves can be worn inside waterproof gloves.[3]

Substitution of less irritating substances, such as emollients and soap substitutes, should be used rather than soap when washing. Moisturizers are thought to increase hydration or prevent TEWL, thereby maintaining skin barrier function and reducing the risk of ICD. Care should be taken for several months after the dermatitis has healed, as the skin remains vulnerable to flares of dermatitis for a prolonged period.[3,26,28]

PROGNOSIS

The prognosis for acute ICD is good if the causative irritant can be identified and eliminated. The prognosis for cumulative or chronic irritant dermatitis is guarded and may be worse than that of ACD.[41] An atopic background, lack of knowledge about the disease, and/or a delayed diagnosis and treatment are factors that lead to a worse prognosis.[14] Persistent post-occupational dermatitis has been seen in 11 percent of individuals.[42]

CHAPTER 47

The Ichthyoses

Philip Fleckman
John J. DiGiovanna

The ichthyoses are a heterogeneous group of skin diseases characterized by generalized scaling. Scaling reflects altered differentiation of the epidermis. In this chapter, the terms *epidermal differentiation*, *keratinization*, and *cornification* will be used synonymously. The name *ichthyosis* is derived from the Greek *ichthys*, meaning "fish," and refers to the similarity in appearance of the skin to fish scales. Both inherited and acquired forms are found. Early reports of ichthyosis in the Indian and Chinese literature date back to several hundred years B.C., and the condition was discussed by Willan in 1808.[1]

Ichthyosis can present at birth or develop later in life. It can occur as a disease limited to the skin or in association with abnormalities of other organ systems. A number of well-defined types of ichthyosis with characteristic features can be reliably diagnosed. However, because of the great clinical heterogeneity and the profound effect of the environment on scaling, a specific diagnosis can be challenging in certain patients and families.

Siemens introduced genetic concepts into the ichthyoses.[2]

Genetic approaches to understanding the ichthyoses have revealed the gene defects underlying many of these genodermatoses.[9–11] A new classification is evolving based on the underlying molecular and genetic bases of these disorders. Knowing which gene is mutated directs us to the underlying pathophysiologic process. Understanding and describing these disorders on the basis of common molecular processes lead to more rational approaches to understanding their pathophysiology and treatment. A listing of the more common and the better understood hereditary ichthyoses according to pattern of inheritance and clinical features is shown in Table 47-1. Grouping these disorders according to underlying abnormality (Table 47-2) facilitates understanding of the clinical phenotypes in terms of underlying mechanism. However, further work is necessary to clearly understand how the gene mutations and resultant protein disruptions result in clinical disease, and, furthermore, how therapeutic interventions can be creatively developed.

ICHTHYOSES AT A GLANCE

- A heterogenous group of skin diseases characterized by generalized scaling and, often, areas of thickened skin.
- Most types are inherited, and these usually present at birth. However, some forms are acquired.
- Scales may vary in size, color, and body site.
- May be accompanied by erythema, abnormalities in other parts of skin, and adnexal structures.
- May be associated with systemic findings, such as failure to thrive, increased susceptibility to infection, atopic dermatitis, neurosensory deafness, neurologic and other disease.
- Pathology is usually non-specific with the exception of epidermolytic hyperkeratosis, neutral lipid storage disease, Refsum disease, and acquired ichthyosis associated with sarcoidosis.

TABLE 47-1
Features of Selected Ichthyoses

Diagnosis	Onset	Characteristic Clinical Features	Associated Features	Gene	Protein	Function	Skin Histopathology
Autosomal semidominant[a]							
Ichthyosis vulgaris (OMIM #146700)	Infancy/childhood	Fine or centrally tacked-down scale with superficial fissuring. Relative flexural sparing; worse on lower extremities. Hyperlinear palms/soles.	Keratosis pilaris; atopy.	*FLG*	Absence of filaggrin	Uncertain	Hyperkeratosis; reduced or absent granular layer.
Autosomal dominant[a]							
EHK (bullous CIE; OMIM #113800)	Birth	Heterogeneous. May have verrucous, firm, hyperkeratotic (hystrix) spines, often linearly arrayed in flexural creases; blisters; may have erythroderma and/or palmar/plantar keratoderma.	Frequent skin infections; characteristic pungent odor.	*KRT1*, *KRT10*; in Vörner type (confined to palms/soles) *KRT9*	Keratin 1 or 10; in Vörner type, keratin 9	Structural protein abnormality leading to keratin intermediate filament dysfunction—epidermal fragility	Hyperkeratosis; vacuolar degeneration of the epidermal granular (and often deeper) layer; large, irregular keratohyalin granules.
Ichthyosis bullosa of Siemens (OMIM #146800)	Birth	Redness and blistering at birth. Later develop hyperkeratosis, accentuated over flexures. Mauserung (molting): Collarette-like lesion where uppermost epidermis has been lost.	—	*KRT2*	Keratin 2, which is expressed in superficial epidermis	As above for EHK	Hyperkeratosis and epidermal vacuolization, similar to EHK but confined to the upper spinous and granular layer.
Ichthyosis hystrix of Curth and Macklin (OMIM #146590)	Birth	Resembles EHK, varies from palmar/plantar keratoderma to generalized. Thick "porcupine-like" spines. No blistering.	—	*KRT1*—mutation in variable region	Keratin 1	As above for EHK	Upper epidermal keratinocytes have perinuclear vacuolization/perinuclear shells of tonofilaments.
Annular epidermolytic erythema (OMIM #607602)	Birth/infancy Annular plaques develop later	Severe, intermittent scaling with blisters or pustules. Evolves to widespread, migratory, annular plaques.	—	*KRT1*, *KRT10*	Keratin 1 or 10	As above for EHK	As above for EHK.
Erythrokeratodermia variabilis (OMIM #133200)							
Generalized type	Birth	Generalized hyperkeratosis and figurate, migratory red patches.	Red patches move over minutes to hours; may be triggered by changes in temperature.	*GJB3* or *GJB4*	Connexin 31 or 30.3; connexins form gap junction channels between cells	Abnormal intercellular communication	Hyperkeratosis, acanthosis, papillomatosis, capillary dilatation; epidermis may have "church spire" appearance.
Localized type	Variable	Localized hyperkeratotic plaques with figurate, migratory red patches.	Hyperkeratotic plaques may be induced by trauma. Considerable intrafamilial variability.				

Progressive symmetric erythrokeratodermia (OMIM #602036)	Shortly after birth	Erythematous, scaly plaques, symmetrically distributed over extremities, buttocks, and face; stabilize in early childhood. Trunk tends to be spared.	—	*LOR*	Loricrin	Cornified envelope formation	Non-specific.
Keratitis, ichthyosis, and deafness syndrome; recessive has been reported (OMIM #148210)	Birth/infancy	Progressive corneal opacification; either mild generalized hyperkeratosis or discrete erythematous plaques, which may be symmetric; neurosensory deafness.	Follicular hyperkeratosis, scarring alopecia, dystrophic nails, susceptibility to infection.	*GJB2*, *GJB6*	Connexins-26, -30; connexins form gap junction channels between cells	Abnormal intercellular communication	Non-specific.
X-linked							
X-linked recessive ichthyosis (OMIM #08100)	Birth/infancy	Fine to large scales; comma-shaped corneal opacities on posterior capsule.	Cryptorchidism; female carriers may have corneal opacities and delay of onset or progression of labor in affected pregnancies.	*STS*	Steroid sulfatase	Lipid metabolism—abnormal cholesterol metabolism with accumulation of cholesterol sulfate	Hyperkeratosis, may have hypergranulosis; non-specific.
Chondrodysplasia punctata X-linked recessive (CDPX; OMIM #302950)	Birth	May begin as erythroderma, linear or whorled atrophic or hyperkeratosis, alopecia, skeletal abnormalities, short stature.	Cataracts, deafness.	*ARSE*	Arylsulfatase E	Lipid metabolism—ill-defined: Failure of hydrolysis of sulfate ester bonds	—
X-linked dominant chondrodysplasia punctata (Conradi-Hünermann-Happle syndrome; CDPX2; OMIM #302960)	Birth	CIE at birth, clears and is replaced by linear hyperkeratosis, follicular atrophoderma and pigmentary abnormalities; stippled calcifications on radiographs.	Occurs almost exclusively in females; hair shaft abnormalities, short stature, cataracts.	*EBP*	EBP—also known as 3β-hydroxysteroid-δ8-δ7-isomerase	Lipid metabolism—post-squalene cholesterol biosynthesis	—
CHILD syndrome X-linked dominant (OMIM #308050)	Birth	Congenital hemidysplasia, ichthyosiform erythroderma, limb defects.	Almost exclusively in females.	*NSDHL*; *EBP* also reported	NSDHL (3 β-hydroxysteroid dehydrogenase); EBP also reported	Lipid metabolism—post-squalene cholesterol biosynthesis	—

TABLE 47-1
Features of Selected Ichthyoses (Continued)

Diagnosis	Onset	Characteristic Clinical Features	Associated Features	Gene	Protein	Function	Skin Histopathology
Autosomal recessive							
ARCI							
ARCI/LI	Birth; often collodion presentation	Large, plate-like, brown scale over most of the body; accentuated on lower extremities. Ectropion; eclabium; alopecia. Palmar/plantar involvement varies.	Heat intolerance.	Various (see Table 47-3)	Various (see Table 47-3)	Various (see Table 47-3)	Hyperkeratosis, acanthosis, may show parakeratosis. Non-specific.
ARCI/CIE	Birth; often collodion presentation	Fine, white scale; generalized erythroderma. Palmar/plantar involvement varies.	Heat intolerance.	Various (see Table 47-3)	Various (see Table 47-3)	Various (see Table 47-3)	Hyperkeratosis, acanthosis, may show parakeratosis. Non-specific.
ARCI/overlap	Birth; often collodion presentation	Varies between "lamellar" and "CIE." Considerable overlap may exist.	Heat intolerance.	Various (see Table 47-3)	Various (see Table 47-3)	Various (see Table 47-3)	Hyperkeratosis, acanthosis, may show parakeratosis. Non-specific.
Harlequin ichthyosis (OMIM #242500)	Birth	Markedly thickened skin with geometric, deep fissures. Survivors develop severe CIE phenotype.	Restricted respiration, poor feeding; neonatal sepsis; often leads to neonatal death. Failure to thrive.	*ABCA12*	ATP-binding cassette, subfamily A, member 12	Lipid metabolism—membrane transport, abnormality of lipid metabolism	Massively thickened, orthokeratotic stratum corneum; variable acanthosis; granular layer variably decreased.
Netherton syndrome (OMIM #256500)	Birth	Ichthyosis linearis circumflexa or similar to CIE; trichorrhexis invaginata.	Atopy; high serum levels of immunoglobulin E; may have aminoaciduria; failure to thrive.	*SPINK-5*	LEKTI (a serine protease inhibitor)	Protein metabolism—may result in premature desmosomal degradation in stratum corneum	Non-specific.
Sjögren-Larsson syndrome (OMIM #270200)	Ichthyosis apparent at birth	Generalized fine scale to coarse hyperkeratosis; spastic diplegia; mental retardation; retinal glistening white dots.	Short stature, seizures.	*FALDH* (*ALDH10*, *ALDH3A2*)	Fatty aldehyde dehydrogenase	Lipid metabolism—fatty aldehyde metabolism	Non-specific.
Refsum disease (OMIM #266500)	Ichthyosis develops in adulthood	Progressive neurologic dysfunction; skeletal, cardiac, and renal abnormalities. Retinitis pigmentosa.	Elevated plasma phytanic acid.	Most *PAHX*; *PEX7* also reported (see RCDP below)	Phytanoyl-CoA hydroxylase	Peroxisome abnormality—deficiency of phytanic acid catabolism; results in phytanic acid accumulation	Lipid-containing vacuoles in basal keratinocytes.
RCDP (OMIM #215100)	Birth	Dwarfism, stippled cartilage calcifications, joint contractures, cataracts, ichthyosis, mental retardation.	Low levels of red cell plasmalogens; accumulation of phytanic acid.	*PEX7*	Peroxin 7 (peroxisomal protein)	Peroxisome abnormality—failure of receptor targeting enzymes to peroxisomes	—

Trichothiodystrophy [Tay syndrome; *PIBI(D)S*, *IBI(D)S*, *BI(D)S)*; OMIM #278730, #601675, #234050]	Some have ichthyosis, which may be apparent at birth; may have collodion presentation	*B*rittle hair, *p*hotosensitivity, *s*hort stature, *i*chthyosis, *i*ntellectual impairment, microcephaly, recurrent infections.	Abnormally low sulfur content of hair.	Majority have defect in *ERCC2* (XPD). A few have mutations in *ERCC3* (XPB), *GTF2H5* (TTDA), or *TTDN1*	Most XPD. XPB, TTDA, or TTDN1 in a few	Components of transcription factor TFIIH	Tiger-tail banding of hair shafts under polarizing microscopy; hair shaft abnormalities (trichoschisis, trichorrhexis nodosa-like fraying; ribboning).
Chanarin-Dorfman syndrome (neutral lipid storage disease; OMIM #275630)	Birth; may be collodion	Generalized scaling, resembles CIE; variable extra-cutaneous involvement: cataracts, decreased hearing, psychomotor delay.	Severe pruritus; neurologic abnormalities; hepatic abnormalities; lipid droplets in circulating leukocytes.	*CGI-58*	Unknown	Lipid metabolism—activates adipose-triglyceride lipase for lipolysis of triglycerides	Lipid droplets in dermal and epidermal cells, and acrosyringia of eccrine ducts.
Multiple sulfatase deficiency (OMIM #272200)	Birth	Ichthyosis resembling X-linked recessive.	Neurologic deterioration; skeletal abnormalities; facial dysmorphism.	*SUMF1*	C_{α}-formylglycine generating enzyme	Generates catalytic residue in active site of eukaryotic sulfatases	Non-specific.
Peeling skin syndrome							
Type A (noninflammatory; OMIM #270300)	Birth	Generalized peeling in superficial, thin flakes.	—	Unknown	Unknown	Unknown	Intracellular split within corneocytes in stratum corneum.
Type A—acral variant (OMIM #609796)	Birth	Limited to over hands and feet.	—	*TGM5*	Transglutaminase 5	Protein cross-linking	Non-specific.
Type B (inflammatory)	Birth	Presents as CIE; evolves to migratory, scaling patches.	Pruritus, elevated immunoglobulin E, aminoaciduria, short stature.	Unknown	Unknown	Unknown	Intercellular split between stratum corneum and granular layer; between keratinocytes.

ARCI = autosomal recessive congenital ichthyosis; ATP = adenosine triphosphate; CIE = congenital ichthyosiform erythroderma; CHILD syndrome = *c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma and *l*imb *d*efects syndrome; CoA = coenzyme A; EBP = emopamil-binding protein; EHK = epidermolytic hyperkeratosis; LEKTI = *l*ympho-*e*pithelial *K*azal-*t*ype related *i*nhibitor; LI = lamellar ichthyosis; NSDHL = *N*AD(P)H *s*teroid *de*h*y*drogenase-*l*ike protein; OMIM = Online Mendelian Inheritance in Man; RCDP = *R*hizomelic *c*hondro*d*ysplasia *p*unctata; SPINK-5 = *s*erine *p*rotease *in*hibitor, *K*azal type *5*; TFIIH = transcription factor IIH.

CLINICAL PRESENTATION

A specific diagnosis in an individual or family with ichthyosis can help to predict prognosis and is important for genetic counseling. Several features are useful in distinguishing different forms of ichthyosis. These include the age of onset, presence of collodion membrane at birth, quality of scale, presence/absence of erythroderma, abnormalities in other parts of the skin (e.g., palms and soles, ectropion, eclabium) and adnexal structures (e.g., alopecia, hair follicle or shaft abnormality), and involvement of other organ systems. In different types of ichthyosis, the appearance of the surface of the skin may vary. Visible scaling (see Chapter 4) may be seen in some patients, with flakes of stratum corneum varying in size from fine to coarse. There may also be a thickening of the skin with or without visible scale. The term *hyperkeratosis* has been used clinically to describe thickened skin, with or without scale, that reflects thickening of the stratum corneum. A family pedigree may clarify the pattern of inheritance. The presence of parental consanguinity may suggest autosomal recessive inheritance. However, many autosomal dominant diseases (e.g., epidermolytic hyperkeratosis) have a high frequency of spontaneous mutation, and the lack of a positive family history does not rule out autosomal dominant inheritance. Light microscopic features are usually diagnostic in epidermolytic hyperkeratoses and can be helpful in selected ichthyoses (e.g., Refsum disease, neutral lipid storage disease, acquired ichthyosis of sarcoidosis), but histopathologic examination may not be useful to distinguish other ichthyoses. In many cases, the clinical diagnosis may be clarified by genetic analysis. The development of ichthyosis in adulthood may be a marker of systemic disease.

ETIOLOGY AND PATHOGENESIS

The fully differentiated end product of the epidermis is the stratum corneum, which is composed of terminally differentiated keratinocytes, corneocytes ("bricks"), surrounded by an intercellular matrix ("mortar") (see Chap. 45). The corneocyte bricks are protein-enriched, and the intercellular mortar is composed of hydrophobic, lipid-enriched membrane bilayers.[8] The keratin-laden corneocytes are thought to be primarily responsible for the resilience and water retention properties of the stratum corneum, while the matrix forms most of the permeability barrier to water loss. The normal stratum corneum undergoes desquamation in an organized and invisible manner, with individual corneocytes separating from each other and shedding as single cells. Ichthyotic skin has an abnormal quality and quantity of scale, the barrier function of the stratum corneum is compromised, and there may be alterations in the kinetics of epidermal cell proliferation (see Chap. 44). The stratum corneum can be viewed as a compartment, with thickening of the stratum corneum being the result of cells entering the compartment at an increased rate, or leaving (corneocyte desquamation) too slowly, or both.

The process of epidermal differentiation is complex and not completely understood. Defects in many different aspects and steps of this process can lead to a similar end result: abnormal stratum corneum and scale. In some of these dis-

orders, the underlying abnormality has been identified. For example, mutations in the genes that encode the suprabasal epidermal keratins, keratins-1 and -10, cause epidermolytic hyperkeratosis.[13] Mutations in the gene encoding transglutaminase 1, an enzyme that catalyzes the cross-linking of proteins and attachment of ceramides during the formation of corneocytes, cause lamellar ichthyosis, one form of autosomal recessive congenital ichthyosis (ARCI).[14–16] The observation that key components of this process cause ichthyosiform disorders highlights the importance and complexity of normal keratinocyte differentiation.

Steroid sulfatase controls the hydrolysis of cholesterol sulfate in corneocytes and is thought to be important in the regulation of corneocyte desquamation. Deficiency of steroid sulfatase causes X-linked recessive ichthyosis.[17,18] The observation that several drugs that lower serum cholesterol (e.g., nicotinic acid, triparanol) can induce ichthyotic skin changes indicates the importance of lipid homeostasis in normal keratinization.[19] Further evidence is the identification of mutations in the genes encoding cholesterol biosynthetic enzymes as a cause of X-linked dominant chondrodysplasia punctata and *c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma and *l*imb *d*efects (CHILD) syndrome and genes encoding other aspects of lipid biosynthesis in the autosomal recessive congenital ichthyoses.[20] The recent identification of mutations in *SPINK-5* (serine *p*rotease *in*hibitor, *K*azal type *5*), encoding a serine protease inhibitor, confirms a role for protease inhibitors in normal epidermal differentiation.[21] The discoveries of connexin abnormalities as causes for erythrokeratodermia variabilis; keratitis, ichthyosis, and deafness (KID) syndrome; and other disorders involving ectodermal tissues highlight the role of intercellular communication for properly functioning skin.[10,22]

These examples highlight the complexity of the process of forming a normally functioning stratum corneum and demonstrate that diverse abnormalities can result in similar clinical phenotypes of thickened stratum corneum and scaling. How do diverse processes result in similar phenotypes? The answers are unclear, although studies suggest that defects in the barrier may result in inflammation and hyperproliferation.[23] Furthermore, our evolving understanding of these mechanisms continues to clarify the multisystem, clinical phenotypes observed in several ichthyosiform disorders.

◀ **FIGURE 47-1** Ichthyosis vulgaris. Full presentation of ichthyosis vulgaris in individuals with mutations in both profilaggrin genes (**A**, **C**, **E**); milder presentation in an individual with a profilaggrin mutation in a single allele (**B**, **D**, **F**). **A and B.** Fine, white scale on lower abdomen. **C–F.** Hyperlinear palms. (From Smith FJ et al: Loss-of-function mutations in the gene encoding filaggrin cause ichthyosis vulgaris. *Nat Genet* **38**:337, 2006, with permission.)

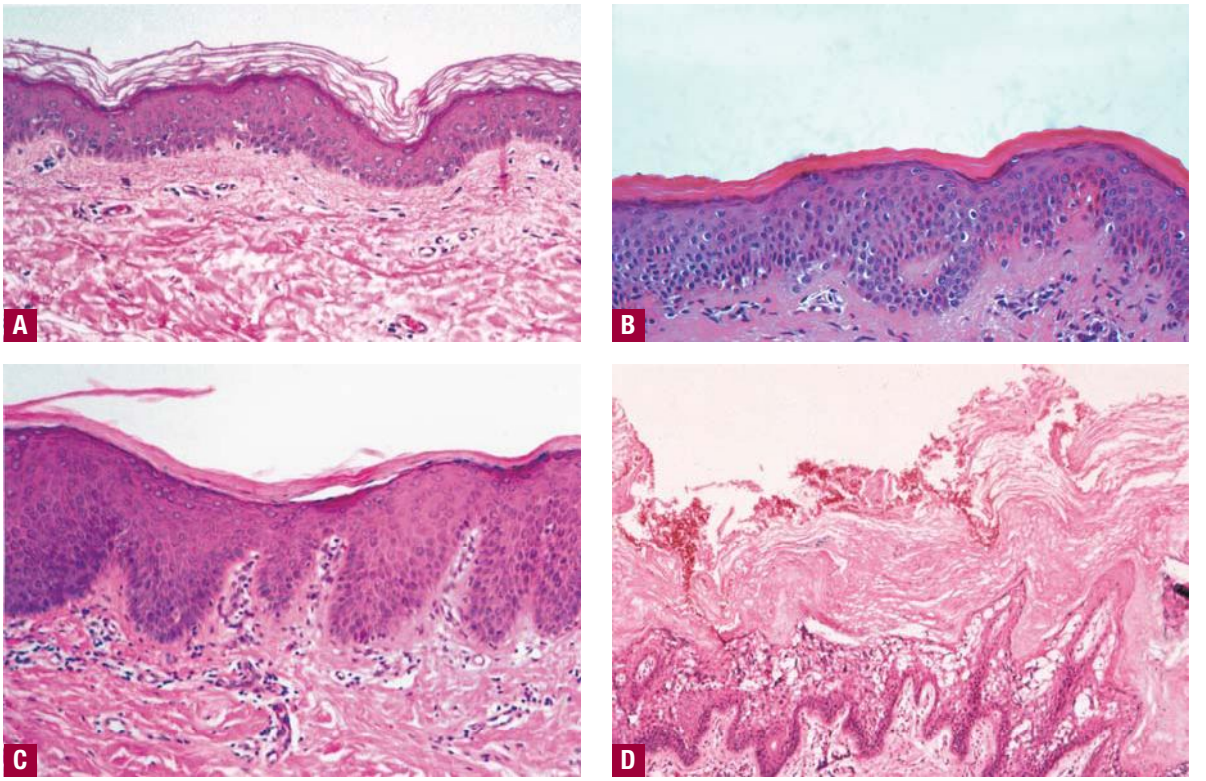
ICHTHYOSIS VULGARIS

Ichthyosis vulgaris (OMIM #146700), the most common ichthyosis, is relatively mild. Although infants usually have normal skin, the disease often manifests within the first year. The scale of ichthyosis vulgaris is usually most prominent on the extensor surfaces of the extremities, with flexural sparing (Fig. 47-1). The diaper area tends to be spared. There may be fine, white scale over large areas. Particularly on the lower extremities, which are often the most severely involved area, the scale may be centrally attached, with "cracking" (superficial fissuring through the stratum corneum) at the edges. This turning up at the edges can lead to the skin feeling rough.

A number of other findings are commonly observed in association with ichthyosis vulgaris.[24] Hyperlinear palms are usually present, and some patients may have palmar/plantar thickening approaching a keratoderma. Keratosis pilaris (a follicular spine–like hyperkeratosis) is common, even in individuals with mild ichthyosis vulgaris, and usually involves the outside of the arms, extensor thighs, and buttocks (see eFig 47-1.1 in on-line edition). Atopy is also frequently observed and can manifest as hay fever, eczema, or asthma. These findings can confound an accurate diagnosis, because hyperlinear palms and keratosis pilaris may be seen in atopic individuals who do not have ichthyosis vulgaris. Rarely, individuals with ichthyosis vulgaris may have hypohidrosis with heat intolerance. There is great variation in the severity of clinical manifestations between affected individuals in the same family. The condition usually worsens in climates that are dry and cold and improves in warm, humid environments, where the disease may clear dramatically.

The disease was thought to be autosomal dominant.[4] Recently, mutations in the gene encoding profilaggrin (*FLG*) have been found to cause ichthyosis vulgaris. This finding clarifies the inheritance pattern as semi-dominant. Individuals who are homozygotes or compound heterozygotes for the mutations (i.e., those with mutations in both profilaggrin alleles) manifest a severe clinical phenotype. Individuals with mutations in one profilaggrin allele (heterozygotes) manifest a mild phenotype with ~60 percent penetrance (see Fig. 47-1). The prevalence of the mutations is ~9 percent, and that of homozygotes is ~1 in 400 in the Anglo European population.[25,26]

It is difficult to distinguish some patients with mild ichthyosis vulgaris from simple dry skin (xerosis). Evolving understanding of this very common condition is beginning to clarify how a spectrum of underlying mutations can cause the diverse clinical severity of dry skin from xerosis to severe ichthyosis vulgaris. In addition, on the basis of skin findings alone, males with severe ichthyosis vulgaris may be difficult to differentiate from those affected with X-linked recessive ichthyosis.[24,27] The histopathologic findings of ichthyosis vulgaris (Fig. 47-2A) may be distinctive in specimens taken



▲ **FIGURE 47-2** Histopathology. **A.** Ichthyosis vulgaris. Note absent granular layer. **B.** X-linked recessive ichthyosis. Note compact hyperkeratosis and accentuated granular layer. (Used with permission from Rob McFarlane, MD.) **C.** Autosomal recessive congenital ichthyosis. Thickened stratum corneum composed of compact hyperkeratosis with foci of parakeratosis. **D.** Epidermolytic hyperkeratosis. The stratum corneum is thickened (hyperkeratosis), and there is prominent vacuolar degeneration of suprabasalar epidermis most marked at the granular layer.

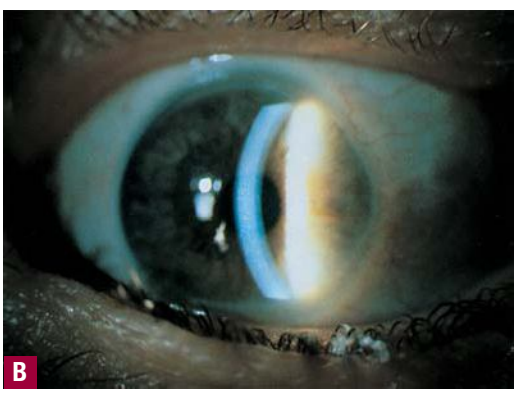
from homozygotes, showing mild hyperkeratosis and absent granular layer. In heterozygotes, even when the granular layer is present on light microscopy, examination by electron microscopy can show keratohyalin granules that are small, abnormally shaped, and crumbly in appearance.[28]

Filaggrin is an epidermal protein that is thought to be important in the aggregation of keratin intermediate filaments[29] and retention of moisture in the stratum corneum.[30] Keratin filaments form a network, or cell matrix, that gives structural integrity to the epidermal keratinocytes. Filaggrin is synthesized as a high-molecular weight precursor, profilaggrin, that contains multiple filaggrin molecules and is localized to keratohyalin granules. Biochemical studies of epidermis from patients with ichthyosis vulgaris have shown absence or decrease of filaggrin and its precursor, profilaggrin.[31] The defective profilaggrin expression is maintained in keratinocytes cultured from subjects with ichthyosis vulgaris.[32] In the Anglo-European population, mutations in *FLG* are very strong predisposing factors for atopic dermatitis. A strong association is also found with individuals who have both asthma and atopic dermatitis.[26]

X-LINKED RECESSIVE ICHTHYOSIS

In the 1960s, X-linked recessive ichthyosis (OMIM #308100) was distinguished clinically from other ichthyoses.[4] Shortly thereafter, the syndrome of placental steroid sulfatase deficiency was described in pregnancies with failure to initiate labor in association with low maternal urinary estrogens. Because the majority of maternal urinary estrogens are derived from the fetal adrenal and are metabolized by the placenta, low levels can reflect fetal abnormalities or death. However, in this condition, low levels do not indicate severe fetal morbidity. The association between failure to initiate or progress labor and ichthyosis in the male offspring was not appreciated until later.[17,18] Steroid sulfatase hydrolyzes sulfate esters, which include cholesterol sulfate and sulfated steroid hormones.[33] Sulfated fetal adrenal hormones undergo desulfation to estrogens, which are excreted in maternal urine. The absence of steroid sulfatase enzyme in the fetal placenta leads to low maternal urinary estrogens and, in some pregnancies, to a failure of labor to initiate or to progress normally. In males with X-linked recessive ichthyosis, steroid sulfatase enzyme activity is decreased or absent in many tissues, including epidermis, stratum corneum, and leukocytes, and in cultured fibroblasts.[34] In addition, cholesterol sulfate, an enzyme substrate, accumulates in serum and in scale. Carrier females have been found to have leukocyte steroid sulfatase levels intermediate between those observed in normal individuals and those in affected males.

X-linked recessive ichthyosis occurs in approximately 1 in 2000 to 6000 males.[4,35] Scaling may begin in the newborn period and is usually most prominent on the extensor surfaces, although there is significant involvement of the flexural areas. Although the extent and degree of scaling are variable, X-linked ichthyosis can usually be distinguished from ichthyosis vulgaris on clinical criteria.[4,36] The latter tends to be associated with hyperlinear palms and soles, keratosis pilaris, and a family history of atopy. X-linked ichthyosis tends to have more severe involvement with larger scale, and comma-shaped, corneal opacities may be present in one-half of adult patients (Fig. 47-3).[37,38] Corneal opacities do not affect vision and may be present in female carriers.[38] Affected males have an increased risk of cryptorchidism and, independently, they are



◀ **FIGURE 47-3** X-linked recessive ichthyosis. **A.** The scales are large and dark and most evident on the flexural areas in this patient. **B.** The blue arc is a cross-section of the cornea as seen by slit-lamp examination. The opacities appear white.

at increased risk for the development of testicular cancer.[39] Histopathologic examination shows compact orthohyperkeratosis, acanthosis, and papillomatosis. The granular layer is usually thickened (see Fig 47-2B).

Cholesterol sulfate levels are elevated in the serum, epidermis, and scale,[40] and there is increased mobility of β-lipoproteins (low-density lipoproteins) on electrophoresis, a feature that can suggest the diagnosis. Steroid sulfatase is one of a group of arylsulfatases located on chromosome Xp22. More than 90 percent of the mutations in X-linked ichthyosis are deletions, explaining the failure to find immunologically detectable enzyme protein in some patients. Deletions can often be detected by fluorescence in situ hybridization, available in many clinical laboratories. Confirmation of the diagnosis can also be made by finding an elevation in serum cholesterol sulfate levels (normal is 80 to 200 μg/dL; X-linked ichthyosis is 2000 to 9000 μg/dL). Unfortunately, cholesterol sulfate determination in serum and scale may not be readily available for laboratory confirmation of the clinical diagnosis. In the rare case in which deletions are not detected and a clinical diagnosis is necessary, arylsulfatase C (steroid sulfatase) enzyme activity can be measured in cultured fibroblasts. Deletions that include adjacent sulfatases explain the overlap syndromes involving chondrodysplasia punctata and X-linked ichthyosis.[41] The X-linked form of Kallmann syndrome, in which hypogonadotrophic hypogonadism and anosmia are found, often with renal abnormalities, obesity, synkinesis (mirror image movements of the extremities), cleft palate, and spastic paraplegia, can also be seen in association with X-linked recessive ichthyosis as part of a contiguous gene deletion syndrome.[42] Because of this, and because of the association with testicular carcinoma, patients with X-linked recessive ichthyosis should be queried about anosmia and have periodic testicular examination.[43.]

In the epidermis, steroid sulfatase catalyzes the hydrolysis of cholesterol sulfate. The identification of steroid sulfatase deficiency in X-linked ichthyosis supports the importance of cholesterol sulfate hydrolysis in normal desquamation. Topical application of cholesterol sulfate in mice can induce a scaling disorder, further supporting the role of cholesterol sulfate hydrolysis in corneocyte desquamation.

A family was described with an ichthyosis inherited in an X-linked pattern but with normal steroid sulfatase activity and the absence of corneal opacities.[44] This demonstrates heterogeneity within X-linked ichthyosis. Because of its frequent occurrence, steroid sulfatase deficiency accounts for most cases of X-linked ichthyosis, but a normal steroid sulfatase level in a male with ichthyosis does not rule out an X-linked pattern of inheritance.

AUTOSOMAL RECESSIVE CONGENITAL ICHTHYOSIS

The term *autosomal recessive congenital ichthyosis* is useful to describe a heterogeneous group of disorders that present at birth with generalized involvement of the skin. ARCI can be syndromic, when accompanied by manifestations in other organ systems, or nonsyndromic. Autosomal recessive ichthyosis is rare and has been estimated to occur in about 1 in 300,000 persons.[4]

In older literature, non-bullous congenital ichthyosiform erythroderma (NCIE, lamellar ichthyosis, with autosomal recessive inheritance) was distinguished from bullous congenital ichthyosiform erythroderma (epidermolytic hyperkeratosis, with autosomal dominant inheritance) based on clinical appearance (bullae) and pattern of inheritance.[6,45] That the term *lamellar ichthyosis* was used interchangeably with NCIE and included a spectrum of phenotypes has led to some confusion. Williams and Elias distinguished lamellar ichthyosis from NCIE [usually called *congenital ichthyosiform erythroderma* (CIE)], a milder erythrodermic form.[46] Some patients with lamellar ichthyosis can be clearly distinguished from those with CIE on the basis of clinical features. In lamellar ichthyosis, one sees large, dark, plate-like scale, and although infants may be red at birth, adults

▲ **FIGURE 47-4** Classic lamellar ichthyosis phenotype. **A.** Ectropion. **B and C.** Large, brown, plate-like scale. (From Russell LJ et al: Linkage of autosomal recessive lamellar ichthyosis to chromosome 14q. *Am J Hum Genet* **55**:1146, 1994, with permission.)

have little to no erythroderma (Fig. 47-4). In the more severe, classic presentation of lamellar ichthyosis, tautness of the facial skin leads to traction on the eyelids and lips, leading to ectropion and eclabium. Scarring alopecia, most prominent at the periphery of the scalp, may be partly due to traction at the hair line. In contrast, CIE has generalized redness and fine, white scale (Fig. 47-5). Patients with classic CIE have little to no ectropion, eclabium, or alopecia. However, many patients do not fit neatly into these two clinical descriptions,[47] in that they have features of both lamellar ichthyosis and CIE and a clinical phenotype intermediate between both disorders. Therefore, it can be useful to consider these two distinctive presentations as ends of a spectrum, between which lie a gradation of clinical phenotypes with variable degrees of erythema and coarseness of scale. Individual features, such as collodion membrane (discussed in Collodion Baby under Ichthyosis in the Newborn), ectropion, and alopecia, can occur across the spectrum. The collodion presentation may, over time, evolve into a disease that falls anywhere within the clinical spectrum of severity and can develop into lamellar ichthyosis, CIE, or have minimal involvement (self-healing collodion baby).[48] Although attempts to refine the categorization of these disorders by using biochemical and ultrastructural observations have failed to yield a consistent and replicable classification scheme,[5] identification of the spectrum of specific molecular defects underlying these conditions will undoubtedly help.

Most patients with lamellar ichthyosis or CIE inherit the disease in an autosomal recessive pattern. Rarely, families have been described with similar phenotypes, where the disease is inherited as an autosomal dominant trait.[5] This is an important consideration for genetic counseling.

LAMELLAR ICHTHYOSIS

Lamellar ichthyosis is apparent at birth, and the newborn usually presents encased in a collodion membrane. At this time, the skin may be red. Over time, the skin develops large, plate-like scales, which appear to be arranged in a mosaic pattern (see Fig. 47-4). In some areas, the scales are centrally attached with raised borders. The scales tend to be largest over the lower extremities, where the large, plate-like scale separated by superficial fissuring can lead to an appearance similar to that of a dry riverbed. During childhood and into adulthood the degree of erythema may vary, but the severe presentation of classic lamellar ichthyosis usually has minimal to no erythroderma. Involvement of the palms and soles in lamellar ichthyosis is variable and ranges from minimal hyperlinearity to severe keratoderma.

The lips and mucous membranes tend to be spared in lamellar ichthyosis, but the adnexal structures may be compromised by the adherent, firm scale. Thick stratum corneum on the scalp tends to encase hairs, and in conjunction with the tautness of the skin, may lead to a scarring alopecia, most marked at the periphery of the scalp. The hyperkeratosis can interfere with normal sweat gland function, resulting in hypohidrosis, but the degree of impairment varies between patients. Some patients have severe heat intolerance and must be vigilant to avoid overheating. Treatment with oral retinoids can improve or prevent some sequelae of lamellar ichthyosis. Patients frequently notice an increase in sweating, with improved heat tolerance. Although retinoid therapy can cause blepharitis or even conjunctivitis, it is usually well tolerated by patients with lamellar ichthyosis. Moreover, the ability of systemic retinoid (and in some cases, topical retinoid) therapy to decrease thick periocular scale can decrease the tendency to develop ectropion. Nevertheless, patients with severe, classic lamellar ichthyosis usually require careful eye maintenance. Because of the ectropion (see Fig. 47-4), the lids may fail to close fully, particularly during sleep; hydration with liquid tears during the day and ophthalmic lubricants at night can prevent exposure keratitis.

Histopathologic examination typically shows orthokeratotic hyperkeratosis with

TABLE 47-3
Genes Identified in Autosomal Recessive Congenital Ichthyosis

Gene[a]	Protein	Function	Systemic Findings
TGM1	Transglutaminase 1	Cornified envelope formation	—
ABCA12	ATP-binding cassette, subfamily A, member 12	Membrane transport/lipid metabolism	—
ALOXE3	Arachidonate lipoxygenase 3	Hydroperoxide isomerase	—
ALOX12B	Arachidonate 12-lipoxygenase, R type	Lipoxygenase	—
ICHYN	Ichthyin	Trioxilin A3 receptor? Hepoxylin pathway?	—
FLJ39501 (CYP4F22)	Cytochrome P_{450}, family 4, subfamily F, polypeptide 2	LTB4-omega-hydoxylase?	—
SNAP29	SNAP receptor (SNARE)	Vesicle transport	CEDNIK syndrome
ABHD5 (CGI58)	Abhydrolase domain containing 5 comparative gene identification-58	Member of esterase/lipase/thioesterase subfamily	Chanarin-Dorfman syndrome

ATP = adenosine triphosphate; CEDNIK = *ce*rebral *d*ysgenesis, *n*europathy, *i*chthyosis, and palmoplantar *k*eratoderma; LTB4 = leukotriene B4; SNAP = soluble N-ethylmaleimide–sensitive factor attachment protein.
[a]The same gene may have more than one name.

mild to moderate acanthosis (see Fig. 47-2C). Rates of epidermal proliferation are normal or only slightly elevated in patients with lamellar ichthyosis, in contrast to those with CIE, which has significantly greater labeling indices.[49]

Genetic linkage studies performed on a group of families affected with the severe phenotype of classic lamellar ichthyosis (large, plate-like scale; ectropion; and minimal to no erythema) found linkage to markers on chromosome 14 in the region of the transglutaminase 1 gene locus.[50] Subsequently, mutations in *TGM1*, the gene encoding transglutaminase 1, were found in several families with lamellar ichthyosis, solidifying the role for transglutaminase 1 in the formation of a normal stratum corneum and its role as a cause of lamellar ichthyosis.[14,15] The transglutaminases catalyze calcium-dependent cross-linking of proteins through the formation of ε-(γ-glutamyl) lysine isodipeptide bonds. During the formation of the stratum corneum, transglutaminase catalyzes the cross-linking of cellular proteins, mostly involucrin, loricrin, and small proline-rich proteins. The resulting protein complex is deposited on the inner side of the plasma membrane to form the cornified envelope. Transglutaminase also attaches ceramides to cornified envelope proteins, notably involucrin, and thereby is important in the formation of both the protein and lipid components of the stratum corneum.[16]

Bathing suit ichthyosis is an unusual form of lamellar ichthyosis in which affected individuals develop the scaling typical of lamellar ichthyosis, but limited to the bathing suit area.[51] The distribution correlates with warmer areas of skin. Decreased transglutaminase is found in these areas, and unique, temperature-sensitive mutations in *TGM1* have been identified in affected individuals.[52]

In a human skin/immunodeficient mouse xenograph model, transfer of a transglutaminase 1 gene into transglutaminase 1–deficient keratinocytes from lamellar ichthyosis patients resulted in normalization of transglutaminase expression and epidermal architecture, in addition to restoration of cutaneous barrier function.[53] Additional disease-causing loci have been found (see Congenital Ichthyosiform Erythroderma).

CONGENITAL ICHTHYOSIFORM ERYTHRODERMA

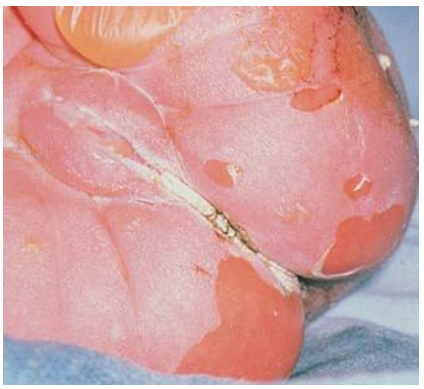
As with lamellar ichthyosis, CIE is apparent at birth, and the newborn usually presents with a taut, shiny, collodion membrane. After shedding of the membrane, the skin of infants with CIE remains red, usually with a fine, white, generalized scale (see Fig. 47-5). On the lower legs, the scale may be larger and darker. In contrast to lamellar ichthyosis, the classic presentation of CIE has little to no ectropion, eclabium, or alopecia. As in lamellar ichthyosis, there is a wide variation in the ability to sweat, and patients with CIE may have minimal sweating with severe heat intolerance. Mucous membranes are usually spared. Palm/sole involvement is variable. Nails may have ridging, but they are often spared. As with all the ichthyoses, dermatophyte infection of the skin and nails is common.

Histopathologic examination shows hyperkeratosis, acanthosis, and often parakeratosis (see Fig. 47-2C). Studies of epidermal proliferation have shown markedly increased epidermal cell turnover, in contrast to lamellar ichthyosis.[49]

A small subset of patients with CIE have been found to have mutations in *TGM1*, and two siblings with a collodion presentation, CIE, and palmoplantar keratoderma had an autosomal dominant mutation in the cornified envelope protein, loricrin.[54] Further genetic heterogeneity within ARCI has been demonstrated, with exclusion of *TGM1* as the disease-causing gene in families with phenotypes within the spectrum of classic lamellar ichthyosis and CIE and identification of mutations in other genes. To date, mutations have been identified in five additional genes in nonsyndromic ARCI, and in two additional genes in two forms of syndromic ARCI. In addition, two other genetic loci (12p11.2-q13 and 19p13.1-13.2) have been found to be associated with ARCI; the responsible genes have not been identified (Table 47-3). A newly described, lipoxygenase pathway has been hypothesized as a common pathway linking many of the ARCIs.[20] This hypothesis remains to be tested, and how the most common mutation in ARCI, that of *TGM1*, might relate to lipid abnormalities is unclear.

EPIDERMOLYTIC HYPERKERATOSIS

In 1902, Brocq described bullous ichthyotic erythroderma and distinguished the blistering type from the nonblistering type of congenital ichthyotic erythroderma.[55] The original description included three unrelated patients whose clinical manifestations varied. However, this was probably the first description of



▲ **FIGURE 47-6** Epidermolytic hyperkeratosis. Newborn showing blistering and erosions.

epidermolytic hyperkeratosis (OMIM #113800). Today, the disease is named for the distinctive histopathologic features of vacuolar degeneration of the epidermis (i.e., epidermal lysis) and associated hyperkeratosis. Epidermolytic hyperkeratosis is also known as *bullous congenital ichthyosiform erythroderma*, an earlier descriptive name signifying the blistering, neonatal presentation, scaling, and redness.

Epidermolytic hyperkeratosis is transmitted as an autosomal dominant trait with a prevalence of approximately 1 in 200,000 to 300,000 persons. However, there is a high frequency of spontaneous mutation, and as many as one-half of the cases have no family history and represent new mutational events.[45] The disease usually presents at birth with blistering, redness, and peeling (Fig. 47-6). With time, generalized hyperkeratosis may develop, which may or may not be associated with erythroderma. Epidermolytic hyperkeratosis skin usually has a characteristic pungent odor, thought to be related to superinfection by mixed flora.

In contrast to most other ichthyoses, the histopathologic picture of epidermolytic hyperkeratosis is distinctive. There are a tremendously thickened stratum corneum and vacuolar degeneration of the upper epidermis, leading to the histologic term *epidermolytic hyperkeratosis* (see Fig. 47-2D). The vacuolar degeneration usually involves the upper epidermis and occasionally all of the suprabasilar keratinocytes. Granular cells exhibit dense, enlarged, irregularly shaped masses that appear to be keratohyalin granules.[6] On electron-microscopic examination, clumping of filaments is observed to begin in the first suprabasal layer. These aggregated filaments are clumps of keratin intermediate filaments that contain the terminal differentiation-specific keratin-1 and keratin-10.[56]

There is striking clinical heterogeneity between epidermolytic hyperkeratosis families. Six distinctive clinical phenotypes have been described.[57] Several clinical features can be useful to distinguish between the different sub-types, including the presence versus absence of severe palmar/plantar hyperkeratosis and of erythroderma, quality of scale, extent of involvement, presence of digital contractures, and gait abnormality (Table 47-4). Three types with no severe palm/sole hyperkeratosis are called *NPS types*. Patients with the NPS-1 clinical phenotype have generalized involvement with thick, brown verrucous hyperkeratosis, most prominent over joints. Palms and soles are spared. Cobblestone or hystrix (porcupine-like) spiny papules are characteristic; this severe clinical presentation is one of the more commonly recognized types of epidermolytic hyperkeratosis (Fig. 47-7A). NPS-2 is similar, but much milder, without the hystrix spines and with relative sparing of the skin between joints (see Fig. 47-7B). Generalized exfoliative erythroderma is found in NPS-3 (see Fig. 47-7C). Three types with severe palm/sole hyperkeratosis are called *PS types*. Patients with the PS-1 type have a smooth palmar/plantar hyperkeratosis with a sharp border, often delineated by a red halo. Blisters may be present at the border. There may be limited involvement of the trunk, usually confined to areas over joints (see Fig. 47-7D). The PS-2 type is characterized by generalized erythroderma and scaling. Volar involvement may be severe, with contractures of the digits and ainhum-like constricting digital bands (see Fig. 47-7E). The PS-3 type has generalized skin involvement with a pebbly hyperkeratosis that is arrayed in a distinctive, cerebriform pattern on the palms and soles (see Fig 47-7F).

Sporadic epidermolytic hyperkeratosis due to a postzygotic, spontaneous mutation during embryogenesis can present in a mosaic pattern of skin involvement. Areas of hyperkeratosis alternating with normal skin are often distributed in streaks along Blaschko's lines (Fig. 47-8A). These may be limited to a few streaks, or there may be many, with widespread, patchy involvement. Unilateral localization can also occur. This clinical mosaic pattern correlates with underlying genetic mosaicism in that keratin mutations characteristic of epidermolytic hyperkeratosis, which were found in lesional skin, were absent in normal skin.[58,59] If the germline is involved, individuals with mosaic epidermolytic hyperkeratosis can transmit the mutation, which leads to generalized epidermolytic hyperkeratosis in affected offspring (see Fig. 47-8B).[59]

TABLE 47-4
Characteristics of Epidermolytic Hyperkeratosis

	NPS-1	NPS-2	NPS-3	PS-1	PS-2	PS-3
Palm/sole hyperkeratosis	–	–	–	+	+	+
Palm/sole surface	Normal	Normal	Hyperlinear, minimal scale	Smooth	Smooth	Cerebriform
Digital contractures	–	–	–	–	+	–
Scale	Hystrix	Brown	Fine, white	Mild	White scale to peel	Tan
Distribution	Generalized	Generalized	Generalized	Localized	Generalized	Generalized
Erythroderma	–	–	+	–	+	–
Blistering	+	+	+	Localized	+	Neonatal
Most common mutation	Keratin-10			Keratin-1		

NPS = types without severe palm/sole hyperkeratosis; PS = types with severe palm/sole hyperkeratosis; – = absent; + = present.

▲ **FIGURE 47-7** Clinical phenotypes of epidermolytic hyperkeratosis. NPS (no severe palm/sole hyperkeratosis) types are shown in **A–C**. **A.** NPS-1. Generalized involvement with thick, brown verrucous hyperkeratosis. Palms are spared. Over the dorsal foot, hyperkeratosis is arrayed in a characteristic cobblestone or hystrix (porcupine-like) pattern. **B.** NPS-2. Brown hyperkeratosis over the trunk and accentuated over joints. Palms are spared. Compared with the verrucous hyperkeratosis in NPS-1, involvement is much milder. On the lower legs, note the blistering, hypertrichosis, and relative sparing of the skin between the joints. **C.** NPS-3. Generalized erythroderma with white scale and hyperkeratosis. PS (severe palm/sole hyperkeratosis) types are shown in the lower section. **D.** PS-1. Palmar and plantar hyperkeratosis with sharp border delineated by a red halo. Blisters are present at the border. Note the relatively smooth surface. There is characteristic involvement at the joints sparing most of the trunk and extremities. **E.** PS-2. Hands (*left* and *center*) of a 15-year-old patient with severe palmar hyperkeratosis and contractures. Flank of same patient (*lower right*) exhibiting generalized erythroderma and scaling. Palms (*upper right*) of a 36-year-old patient with severe palmar hyperkeratosis, contractures, and ainhum-like constricting digital bands. The palmar hyperkeratosis limits spreading of the fingers. **F.** PS-3. Hyperkeratosis in a cobblestone pattern on the knees. Four-year-old patient with hyperkeratosis in a distinctive cerebriform pattern on the palms and soles (not shown). (Adapted from DiGiovanna JJ, Bale SJ: Clinical heterogeneity in epidermolytic hyperkeratosis. *Arch Dermatol* **130**:1026, 1994,with permission.)

▲ **FIGURE 47-8** Mosaic epidermolytic hyperkeratosis. **A.** Streaks of hyperkeratosis distributed along Blaschko's lines in a sporadic case due to postzygotic occurrence of new mutation. **B.** Grandchild of patient shown in **A**. If the germ line is involved generalized involvement can be transmitted to subsequent generations in an autosomal dominant inheritance pattern.

Within keratinocytes, keratin intermediate filaments form an elaborate network that confers structural stability to the cells. In the suprabasilar differentiating keratinocytes of interfollicular epidermis, this network is formed by keratin-1 and keratin-10. In epidermolytic hyperkeratosis, failure of this network leads to keratinocyte fragility (particularly of the upper epidermis), easy blistering, abnormal epidermal kinetics (hyperproliferation), and thickened stratum corneum (hyperkeratosis). Keratin-10 is the co-expressed partner of keratin-1, both of which are required to form keratin intermediate filaments in the cells of the suprabasal layers of the epidermis (see Chap. 44). Genetic linkage studies[60] and sequencing of the keratin-1 and keratin-10 genes of a number of epidermolytic hyperkeratosis families have identified mutations in either keratin-1 or keratin-10.[56,57] In most cases, palmar plantar involvement implies mutations in keratin-1; this may reflect the "redundancy" of keratin-9 (a keratin that occurs only in the suprabasal epidermis of palmar and plantar skin) and keratin-10 in palmar/plantar epithelium. Mutations in keratin-9 have been found in families with the type of epidermolytic hyperkeratosis limited exclusively to the palms and soles (Vörner) (see Chap. 48).[61]

DISORDERS RESEMBLING EPIDERMOLYTIC HYPERKERATOSIS

Ichthyosis Bullosa of Siemens

Ichthyosis bullosa of Siemens (OMIM #146800) is a rare autosomal dominant genodermatosis that is similar in clinical appearance to epidermolytic hyperkeratosis. Patients are born with redness and blistering. The redness subsides over the subsequent weeks to months while the skin develops dark gray hyperkeratosis, particularly over flexural areas. In some areas, there may be a lichenified appearance to the skin. As with epidermolytic hyperkeratosis, the epidermis is fragile; however, the fragility is more superficial. This can result in loss of the uppermost epidermis (predominantly stratum corneum), yielding a characteristic, collarette-like depressed area that has been described as "mauserung" (molting). Histologically, the epidermis shows hyperkeratosis and vacuolization similar to epidermolytic hyperkeratosis, but it may be confined to the granular layer. In four families with ichthyosis bullosa of Siemens and two originally diagnosed with epidermolytic hyperkeratosis but who lacked mutations in keratin-1 and keratin-10, mutations were found in the gene encoding keratin-2 a differentiation-specific keratin of the suprabasilar epidermis that is expressed in the more superficial epidermal layers.[62]

Ichthyosis Hystrix of Curth and Macklin

Ichthyosis hystrix of Curth and Macklin (OMIM #146590) is a rare, autosomal dominant disorder that clinically resembles epidermolytic hyperkeratosis. Clinical expression varies, even within families, from palmoplantar keratoderma to a severe generalized involvement. There can be widespread patchy, thick, gray-brown hyperkeratosis, most marked on the extensor arms and legs. Patients with extensive involvement resemble those with severe epidermolytic hyperkeratosis without palmar/plantar involvement, with verrucous or porcupine-like (hystrix) hyperkeratosis. However, in contrast to epidermolytic hyperkeratosis, blistering does not occur. Histologic examination of the epidermis shows acanthosis, papillomatosis, and severe orthokeratotic hyperkeratosis, with frequent binucleate cells. Keratinocytes within the granular and upper spinous layers may have perinuclear vacuolization, and some have prominent perinuclear shells. On electron microscopy, there are concentric, unbroken shells of tonofilaments surrounding the nucleus. Study of a three-generation family with ichthyosis hystrix of Curth and Macklin identified a mutation in the variable tail domain (V2) of the keratin-1 gene. Structural analyses of the resulting keratin-1 abnormality showed a failure of keratin intermediate filament bundling, retraction of the cytoskeleton from the nucleus, and failure of localization of loricrin to desmosomal plaques.[63]

Annular Epidermolytic Erythema

Annular epidermolytic erythema (cyclic ichthyosis with epidermolytic hyperkeratosis) (OMIM #607602) presents at birth or in the first few months afterward with severe, intermittent scaling and blistering that resolves during puberty.[64] Residual, limited thickened

▲ **FIGURE 47-9** Collodion baby. The infant is 36 hours old and is covered with a macerated membrane that shows fissures; note ectropion and eclabium. The condition may develop over time into various clinical phenotypes, including autosomal recessive congenital ichthyosis and self-healing collodion baby (see Table 47-5).

plaques of verrucous scale in linear rows can be seen in flexural and intertriginous skin. In some cases, explosive bouts of widespread erythema with blisters and pustules are seen.[65] Patients subsequently develop widespread, migratory, polycyclic, and annular scaling plaques. Light and electron microscopy reveals findings of epidermolytic hyperkeratosis. Mutations in the rod portion of keratin-10[66] and the helix termination of keratin-1[65] have been found.

ICHTHYOSIS IN THE NEWBORN

Collodion Baby

A collodion baby is the usual presentation of ARCI (Fig. 47-9). Less commonly, a collodion presentation can also be seen in infants with several other forms of ichthyosis and, rarely, Gaucher disease (Table 47-5). The child is born encased in a translucent, parchment-like membrane that is taut and may impair respiration and sucking. The spectrum of involvement is probably variable, but has not been well characterized. In addition, the birth is often premature, which adds to morbidity. During the first 2 weeks of life, the membrane breaks up and peels off, often leaving fissures, with impairment of the barrier to infection and water loss. This can lead to difficulties in thermal regulation, an increased risk of infection, and hypernatremic dehydration.[67] Newborn care should include careful monitoring of temperature, hydration, electrolytes, and for infection. Measures to keep the peeling membrane soft and lubricated to facilitate flexibility and desquamation should be used. Appropriate pain management and eye care should be employed, when indicated. These newborns usually benefit from a humidified incubator where the air is saturated with water; wet compresses followed by bland lubricants can be used to further hydrate the membrane and achieve maximum pliability.[68] If, during peeling, residual areas of the membrane are allowed to dry and harden in areas such as the extremities, the taut membrane can constrict and lead to distal swelling. Collodion presentation can develop into a wide spectrum of ichthyotic phenotypes as the child grows (see Table 47-5). In addition, an autosomal recessive, self-healing collodion baby has been described, where the skin clears within the first few weeks and transitions into normal skin thereafter.[48] A *TGM1* mutation sensitive to increase hydrostatic pressure (such as might be found in utero) has been found in one family with two affected children with a history of self-healing collodion membranes.[69]

TABLE 47-5
Disorders Associated with Collodion Membrane

- AEC syndrome
- Autosomal recessive congenital ichthyosis (lamellar ichthyosis, congenital ichthyosiform erythroderma, overlap)
- Chondrodysplasia punctata
- Gaucher disease
- Loricrin keratoderma[a]
- Neutral lipid storage disease
- Self-healing collodion baby
- Sjögren-Larsson syndrome
- Trichothiodystrophy
- X-linked hypohidrotic ectodermal dysplasia
- Other

[a]Mutilating keratoderma with ichthyosis (Vohwinkel syndrome without deafness).
AEC = *a*nkyloblepharon-*e*ctodermal defect-*c*left lip and/or palate.
Note: This table does not distinguish the frequency in which collodion membrane is found in the different disorders listed. In some cases, severe peeling may be mistaken for collodion membrane.[167]

The newborn affected with one of the more severe, generalized types of epidermolytic hyperkeratosis usually has erythema, blistering, widespread erosions, and denuded skin. Because there is a high frequency of new mutations, the disease may be unexpected, and the diagnosis may be unknown. Epidermolysis bullosa or staphylococcal scalded-skin syndrome may be suspected, and the infant treated with antibiotics. The newborn may require intensive care with fluid and electrolyte monitoring. Specialized skin care can minimize blistering and enhance healing of erosions and should include lubrication (to decrease friction as well as mechanical trauma), protective padding, and specialized wound dressings. The newborn with extensive erosions is prone to bacterial infection and sepsis, and carefully chosen topical and systemic antibiotics can minimize the extent of infection.

Harlequin Ichthyosis

A dramatic, severe, and often fatal presentation of ichthyosis is that of harlequin ichthyosis (OMIM #242500, Fig. 47-10). The child is often premature and born with massive, shiny plates of stratum corneum separated by deep, red fissures that tend to form geometric patterns, as seen in the patched costumes of the harlequin clowns from the Italian Commedia dell'Arte dating from the sixteenth and seventeenth centuries. There are poorly developed or absent ears and marked ectropion and eclabium. The first report is from the diary of Rev. Oliver Hart, of Charleston, South Carolina, who described these features in 1750.[70] These children are at great risk during the neonatal period and often die shortly after birth. Abnormal water loss through the skin and poor temperature regulation lead to risk of fluid and electrolyte imbalance. The infants are also at risk for infection beginning in the skin, but at the same time (because of poor temperature regulation) do not show the usual signs of infection. Normal respiration may be restricted by the taut skin. Treatment

▲ **FIGURE 47-10** Harlequin ichthyosis. Note rudimentary ears and the distorted appearance as a result of the thick "plates" of stratum corneum. This baby died a few days after birth.

with systemic retinoids during the newborn period can facilitate desquamation of the membrane.[71,72] Advances in neonatal intensive care, together with facilitating desquamation by judicious use of systemic retinoid therapy, have led to improvements in survival and to the use of the name *harlequin baby* rather than *harlequin fetus*. Some babies have suffered from failure to thrive and require tube feeding. The skin of those who survive the newborn period usually resembles a severe phenotype of CIE.[71,72]

In harlequin ichthyosis, normal lamellar granules are not found; instead, there are small vesicles that lack internal structure. There is also no evidence of the lipid lamellae that form between granular and cornified cells as a result of discharge of lamellar granule contents into the intercellular space.[73] Occurrence of harlequin ichthyosis in consanguineous families suggests autosomal recessive inheritance.[74] Mutations in *ABCA12*, which codes for an adenosine triphosphate-binding cassette transporter involved in lamellar granule secretion and epidermal lipid transport, have been shown to underlie harlequin ichthyosis.[75–77] Mutations in *ABCA12* have also been identified in a subset of individuals with ARCI (see Table 47-3).[78]

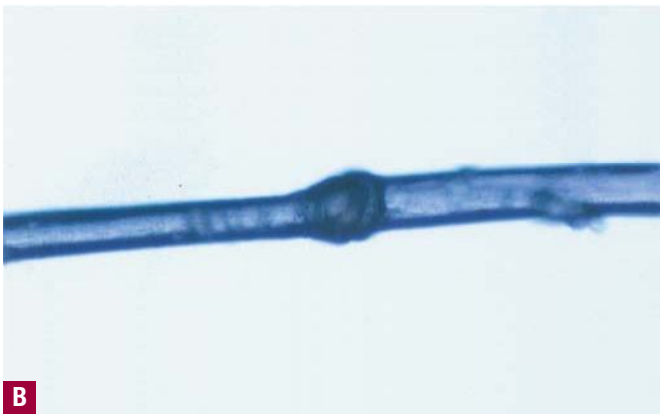
LESS-COMMON ICHTHYOSES

Netherton Syndrome

Netherton syndrome (OMIM #256500) is a rare, autosomal recessive disorder characterized by the concurrence of ichthyosis, a structural hair shaft abnormality, and atopy.[79,80] The usual cutaneous manifestation is ichthyosis linearis circumflexa, a distinctive condition of generalized hyperkeratosis and polycyclic and serpiginous erythematous plaques with a characteristic, migratory, double-edged scale at the margins (Fig. 47-11A). At birth, affected children may present with generalized erythroderma. Infants and children may have feeding problems, with poor absorption and failure to thrive.[81] With atopic dermatitis, there may be pruritus, and scratching can lead to lichenification at the flexures. In some patients, the ichthyosis resembles lamellar ichthyosis or CIE.[5,79] Histopathologic examination is not specific and may show features of hyperkeratosis, psoriasis, and atopic dermatitis. Most patients have a specific hair shaft abnormality called *trichorrhexis invaginata*, in which the distal hair segment is telescoped into the proximal one, forming a ball-and-socket–like deformity on microscopic examination (see Fig. 47-11B). This is also known as "bamboo hair" and is due to abnormal cornification of the internal root sheath. Hair from multiple areas should be examined, because only 20 percent to 50 percent of hair may be affected, and the characteristic abnormality may be (see Chap. 86) more commonly observed on eyebrow hair.[82] Trichorrhexis nodosa and pili torti may also occur. The hair defects may not be detectable at birth, and may disappear with age. Atopy in these patients may manifest as atopic dermatitis, asthma, or severe food allergy (particularly to nuts), and marked elevations of serum immunoglobulin E may occur. In some patients, a generalized aminoaciduria, mild developmental delay, and impaired cellular immunity may also be present. Netherton syndrome has been found to be due to mutations in *SPINK-5*, a gene encoding LEKTI (*l*ympho-*e*pithelial *K*azal-*t*ype related *i*nhibitor).[21] LEKTI is a serine protease inhibitor that is predominantly expressed in epithelial and lymphoid tissues, and may be important in the downregulation of inflammatory pathways. This discovery highlights the importance of the regulation of proteolysis in the overlap between epithelial barrier function and the hypersensitivity of atopy. Subsequently, LEKTI was associated with common atopy and atopic dermatitis.[83] Prenatal testing for Netherton syndrome using molecular data has been successfully accomplished.[84] Tacrolimus ointment, a topical immunosuppressant, is effective in common atopic dermatitis with minimal systemic absorption. However, Netherton syndrome is complicated by an abnormal skin barrier, allowing increased percutaneous absorption and associated risk for systemic toxic effects. This should be considered when using topical agents such as tacrolimus, where monitoring of serum levels may be necessary,[85] and topical steroids, where iatrogenic Cushing syndrome has been reported.[86]

Sjögren-Larsson Syndrome

In 1957, Sjögren and Larsson reported on 13 families from north Sweden with a syndrome of congenital ichthyosis, spastic paralysis, and mental retardation. Sjögren-Larsson syndrome (SLS; OMIM #270200) is a rare, autosomal recessive disorder that presents at birth with an ichthyosis that may range from fine scaling to generalized hyperkeratosis. Erythema may be present at birth but tends to gradually clear by 1 year of age. Collodion-like membranes are rarely seen. The ichthyosis manifests as fine scale, large scale, or a thickening of the stratum corneum without scale and may be pruritic. Thickened areas may be yellow to brown in color and have a lichenified appearance with accentuated skin markings. The most involved areas are the sides and back of the neck, lower abdomen, and flexures. Hair, nails, and the ability to sweat are generally normal.[87] During the first 2 to 3 years, neurologic manifestations of spastic diplegia or tetraplegia and mental retardation develop and can be accompanied by speech defects and seizures. A characteristic ophthalmologic finding is the presence of glistening white dots in the macula of the retina; these occur after 1 year of age and may not be present in all patients. Histologic findings of hyperkeratosis, papillomatosis, acanthosis, and a mildly thickened granular layer are non-specific. Electron-microscopic examination of the skin shows lamellar membranous inclusions in the granular and cornified cells.



▲ **FIGURE 47-11** Netherton syndrome. **A.** Ichthyosis linearis circumflexa showing typical annular lesions. (Used with permission from James Stroud, MD.) **B.** Bamboo hair shaft shows features of trichorrhexis invaginata.

Rizzo et al. linked SLS to fatty alcohol: NAD oxidoreductase (FAO) deficiency. FAO is a complex enzyme with two separate proteins that sequentially catalyze the oxidation of fatty alcohol to fatty aldehyde and subsequently to fatty acid. Further work identified the fatty aldehyde dehydrogenase (FALDH) activity in cultured fibroblasts from patients with SLS component as the affected component of FAO in SLS. FALDH is a microsomal enzyme that catalyzes the oxidation of medium- and long-chain aliphatic aldehydes derived from metabolism of fatty alcohol, phytanic acid, ether glycerolipids, and leukotriene B4.[88] Mutations found in the FALDH gene (*ALDH10*, recently renamed *ALDH3A2*) of three unrelated SLS patients confirmed the role for this enzyme in the etiology of this disorder and the importance of this pathway for normal desquamation.[89] Most mutations are specific to families, although several common mutations suggest founder effect or favored sites for mutation.[90]

The identification of decreased fibroblast FAO activity in a family with atypical cutaneous findings (lack of ichthyosis or discrete plaques rather than generalized ichthyosis) has expanded the spectrum of clinical phenotypes associated with abnormal FAO activity.[91]

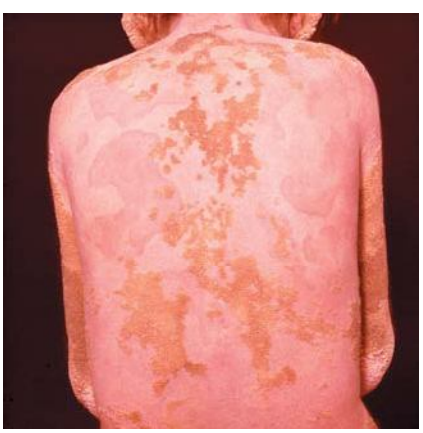
Erythrokeratodermias

The erythrokeratodermias are a clinically and genetically heterogeneous group of disorders characterized by hyperkeratosis and localized erythema. Within a broad spectrum of phenotypes, at least two disorders can be delineated: erythrokeratodermia variabilis and progressive symmetric erythrokeratodermia. There are overlapping clinical features and phenotypic variability within these two designations.[92]

ERYTHROKERATODERMIA VARIABILIS Erythrokeratodermia variabilis (OMIM #133200), described by Mendes da Costa in 1925, is a rare disorder that usually presents at birth or during the first year of life. Both autosomal dominant and recessive inheritance have been described.[93] At least two distinct clinical presentations can be distinguished. One type (Fig. 47-12) is characterized by generalized, persistent, red-brown hyperkeratotic plaques and accentuated skin markings. A second, localized type has involvement that is limited in extent and characterized by sharply demarcated, hyperkeratotic plaques; these are symmetrically arrayed and remain relatively fixed for months to years. In the localized type, there may be considerable variability between affected family members, and the disorder may not be apparent until later in life. Both types are characterized by striking, sharply demarcated, migratory red patches, which vary in size from a few to many centimeters and appear or regress over minutes to hours; some individuals complain of burning at these sites, although in others, they are asymptomatic. Both types of skin lesions may be triggered by trauma to the skin or change in temperature. Palmoplantar hyperkeratosis may be present in either type, but hair, nails, and mucous membranes are unaffected. Histopathologic features are non-specific and include hyperkeratosis, acanthosis, papillomatosis, and capillary dilatation. Epidermis involved with severe papillomatosis and suprapapillary thinning may result in a "church spire" appearance.

Several variants have been described. Erythrokeratodermia en cocardes was described in a family in which the erythematous component was in a target-like configuration.[94] In a possible clinical variant of erythrokeratodermia en cocardes, erythema gyratum repens–like erythema (see Chap. 154) was described in a large kindred.[95] Another family with erythema annulare centrifugum–like lesions (see Chap. 42) has also been described.[96] A child with atypical erythrokeratodermia with neurosensory deafness, bilateral talipes (clubfoot) deformity, and neuropathy was described in which the erythematous component changed only slowly over the year.[97] Erythrokeratodermia with ataxia (Giroux-Barbeau type) is an autosomal dominant disorder that presents during infancy with well-defined, symmetric hyperkeratotic plaques and underlying erythema distributed over the extensor surface of the extremities.[98] Skin lesions regress during adulthood while a progressive spinocerebellar ataxia develops.

Both the localized type of erythrokeratodermia variabilis and erythrokera-



▲ **FIGURE 47-12** Erythrokeratodermia variabilis. Generalized type with widespread hyperkeratosis and migratory, figurate, red patches.

todermia with ataxia have been mapped to a common region (chromosome 1p34-35).[99] Subsequently, Richard et al. found mutations in *GJB3*, the gene encoding connexin-31, in four families with erythrokeratodermia variabilis.[100] Connexins are a family of proteins that form gap junctions, which are important channels for intercellular communication. This intercellular signaling system is crucial for maintaining tissue homeostasis, growth control, development, and synchronized response of cells to stimuli. The identification of connexin mutations as the cause of erythrokeratodermia variabilis implicates this pathway in epidermal differentiation and in the mechanism of skin response to external factors. Different mutations in the same connexin-31 gene (*GJB3*) have been found in other patients with deafness and also in some with peripheral neuropathy. Mutations in the related connexin-30.3 (*GJB4*) have been found in other families with erythrokeratodermia variabilis[101]; in the variants with erythema gyratum repens-like erythema that have been studied, connexin-30.3 mutations appear to be found exclusively.[93]

PROGRESSIVE SYMMETRIC ERYTHROKERATODERMIA Progressive symmetric erythrokeratodermia (OMIM #602036), first definitively described by Darier in 1911,[102] is characterized by well-demarcated, erythematous, hyperkeratotic plaques that are symmetrically distributed over the extremities and buttocks, and often the face.[103] The trunk tends to be spared, but palms and soles may be involved. The plaques appear shortly after birth, progress slowly during the first few years, and then stabilize in early childhood. The plaques usually remain stable in location and appearance but may undergo partial regression at puberty. The variable, migratory erythema that defines erythrokeratodermia variabilis is absent. The disorder is inherited in an autosomal dominant pattern but with incomplete penetrance and variable expressivity. A mutation in the cornified envelope protein loricrin was found in one family,[104] although the diagnosis (and the distinction from erythrokeratodermia variabilis) has been disputed.[105]

Keratitis, Ichthyosis, and Deafness Syndrome

KID syndrome (OMIM #148210) is a rare disorder characterized by *k*eratitis (with progressive corneal opacification), *i*chthyosis, and *d*eafness (neurosensory). Involvement of multiple ectodermal tissues qualifies KID syndrome as an ectodermal dysplasia. Most cases are compatible with autosomal dominant inheritance. However, occurrence in an inbred sibship suggests the existence of an autosomal recessive form. The disease is characterized by discrete erythematous plaques, and there may be a mild, generalized hyperkeratosis. The distinctive plaques may have a discrete border and a verrucous appearance with crusting and may be conspicuously figurate and symmetric on the face (Fig. 47-13). Furrowing about the mouth results in characteristic faces. There may be prominent follicular hyperkeratosis, which can result in a scarring alopecia of the scalp. "Leather-like" palmar/plantar keratoderma is almost always seen (see eFig. 47-13.1 in on-line edition).[106] Several authors have suggested that because the plaques do not scale, this disorder is more accurately designated an erythrokeratodermia rather than an ichthyosis.[5,106] Descriptions of nail changes vary from absent, delayed appearance after birth, atrophic, or brittle to thickened, with loss of or "rough" cuticles, subungual hyperkeratosis, and leukonychia. The teeth may be small. Auditory evoked potential studies allow detection of the hearing deficit in infancy. Affected individuals can have an increased susceptibility to bacterial, fungal, or viral infections. Squamous cell carcinoma of the skin and tongue has also been reported. In contrast to many other ichthyotic conditions, treatment of these patients with oral retinoids has been reported to be of little benefit and possibly to exacerbate the corneal neovascularization.

Richard et al. discovered dominant mutations in *GJB2*, the gene encoding connexin-26, in eight sporadic cases and one family with KID syndrome. Functional studies of cells expressing mutated connexin-26 demonstrated failure of a fluorescent tracer to pass through gap junction channels to neighboring cells, consistent with disruption of intercellular communication.[22] Different mutations in the same gene (*GJB2*) encoding connexin-26 have also been found in a family with a mutilating palmoplantar keratoderma (Vohwinkel syndrome) and deafness (without ichthyosis)[107] (discussed in Chap. 48), and a mutation in *GJB6*, the gene for connexin-30, has been demonstrated in one child with KID syndrome.[108] Connexin proteins aggregate to form gap junction channels, which span the cell membrane between adjacent cells. These channels are flexible structures that are constantly remodeled, and enable a direct cytoplasmic connection that allows the passage of a variety of small molecules between cells. The identification of mutations in the genes encoding a variety of connexin proteins has highlighted the role of connexin-mediated intercellular communication through gap junctions in the development and maintenance of ectodermal tissues. Connexins-26, -30, and -31 are expressed in the stratified epithelia of the cochlea and epidermis, and abnormalities in these proteins can cause sensorineural hearing impairment and/or skin disorders.[10]

Refsum Disease

Refsum disease (heredopathia atactica polyneuritiformis) (OMIM #266500) is a rare, progressive, degenerative disorder of lipid metabolism resulting from the failure to break down dietary phytanic acid and its subsequent accumulation in tissues. This autosomal recessive condition affects mostly the Scandinavians and populations originating from northern Europe. Clinical manifestations include retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia, cranial nerve dysfunction (neural deafness, anosmia), miosis, electrocardiographic abnormalities, cardiomyopathy, renal tubular dysfunction, and skeletal abnormalities (epiphyseal dysplasia). Ichthyosis, which is variable, generally develops in adulthood after the neurologic and ophthalmologic manifestations. Often, there are small white scales over the trunk and extremities resembling ichthyosis vulgaris. Routine hematoxylin and eosin histologic examination shows variably sized vacuoles in the epidermal basal and suprabasal cells, which corre-

spond to lipid accumulation seen with lipid stains of frozen sections.[109]

Phytanic acid (a 20-carbon, branched-chain fatty acid) is derived from a variety of dietary sources, including dairy products, ruminant fats, and chlorophyll-containing foods; although chlorophyll-bound phytol cannot be absorbed in humans. The disease is caused by a deficiency of phytanoyl-coenzyme A hydroxylase (PhyH), a peroxisomal protein that catalyzes the α-oxidation of phytanic acid. This is the first step in the breakdown of phytanic acid, and PhyH deficiency leads to the accumulation of phytanic acid in the serum and tissues, where it substitutes for the fatty acids normally present. Although mutations in *PAHX*, the gene encoding PhyH, are responsible for most cases of Refsum disease[110] there is genetic heterogeneity.[111] Some affected patients have mutations in the *PEX7* gene, which is the same gene mutated in rhizomelic chondrodysplasia punctata (RCDP; see Rhizomelic Chondrodysplasia Punctata). Refsum disease is distinguished from infantile Refsum disease, a fulminant generalized peroxisomal biogenesis disorder in which young children present with severe neurologic abnormalities, mental retardation, hepatomegaly, and dysmorphic features in addition to the other signs of adult Refsum disease.[112]

The diagnosis can be made by detection of elevated levels of plasma phytanic acid. In children who do not have elevated plasma levels of phytanic acid, the diagnosis may be made by measuring PhyH activity in cultured fibroblasts.[112] Treatment includes dietary restriction of foods containing phytanic acid and its precursors and can include plasmapheresis or lipapheresis. In the clinical setting of a delayed onset of ichthyosis in association with neurologic impairment, this disease should be considered because therapy can arrest progression.

Chondrodysplasia Punctata

Chondrodysplasia punctata is a clinically and genetically diverse group of rare diseases, first described by Conradi, that share the features of stippled calcification of the epiphyses and skeletal changes. They are characterized by abnormal deposition of calcium in the areas of enchondral bone formation during fetal development and early infancy. Several forms also include ichthyosiform changes. Clinical severity ranges from severe dwarfism and death during infancy to a self-limited radiographic abnormality in others. An autosomal recessive (rhizomelic) type and both X-linked dominant[114] and recessive forms[115] have been described. The validity of the originally described autosomal dominant Conradi-Hünermann type has been questioned, because some reported cases were later shown to belong to the X-linked dominant type, and occurrences previously considered sporadic have subsequently been recognized as resulting from warfarin (Coumadin) anticoagulant embryopathy.[114,116]

RHIZOMELIC CHONDRODYSPLASIA PUNCTATA RCDP (autosomal recessive; OMIM #215100) is also known as *peroxisomal biogenesis disorder complementation group 11*. It is a rare, multisystem developmental disorder characterized by dwarfism due to symmetric shortening of the proximal long bones (i.e., rhizomelia), specific radiologic abnormalities (i.e., the presence of stippled calcifications of cartilage, vertebral body clefting), joint contractures, congenital cataracts, ichthyosis, and severe mental retardation. Skin changes are present in approximately 25 percent of patients. Patients have low levels of red cell plasmalogens and accumulation of phytanic acid, starting with normal levels at birth and increasing to more than 10 times normal by age 1 year.

X-LINKED RECESSIVE CHONDRODYSPLASIA PUNCTATA X-linked recessive chondrodysplasia punctata (OMIM #302950) can involve skin (linear or whorled atrophic or ichthyosiform hyperkeratosis, follicular atrophoderma; may begin as erythroderma; Fig. 47-14), hair (coarse, lusterless, cicatricial alopecia), short stature and skeletal abnormalities, cataracts, and deafness. Curry et al. studied a family who had atypical ichthyosis and elevated cholesterol sulfate in two affected males and identified an X chromosomal deletion (Xp22) that included the gene for steroid sulfatase.[115] There is a cluster of arylsulfatase genes at this location. Mutations in *ARSE*, the gene encoding the enzyme arylsulfatase E, were found in five patients; however, it is possible that the disorder may also be caused by mutations in adjacent arylsulfatase genes.[118] The similarity to warfarin embryopathy suggests that warfarin embryopathy may be due to drug-induced inhibition of the same enzyme.

X-LINKED DOMINANT CHONDRODYSPLASIA PUNCTATA Happle and co-workers identified X-linked dominant chondrodysplasia punctata (CDPX2; Conradi-Hünermann-Happle syndrome; OMIM #302960) as a distinct variant characterized by a mosaic pattern of skin involvement and occurrence almost exclusively in females, with loss of the gene function hypothesized to be lethal to males.[114] Affected females have a normal life expectancy, and there may be increased disease expression in successive generations (anticipation). Occurrence in a male has been observed in association with a 47,XYY karyotype. CDPX2 presents at birth as a CIE that clears over months and is replaced by linear hyperkeratosis, follicular atrophoderma, and pigmentary abnormalities. Happle hypothesized that the linear involvement is due to mosaic X-chromosome inactivation (lyonization). Hair shaft abnormalities and cicatricial alopecia can also occur. Stippled calcifications are seen in radiographs of areas of endochondral bone formation during childhood but may no longer be visible after puberty. Stature may be short, with asymmetric shortening of the legs. Cataracts occur, usually asymmetrically, in about two-thirds of patients. Histochemical staining for calcium may show calcifications within the epidermis, especially within hair follicles in young children, which may not be present in older children.[119] Mutations in the gene encoding the emopamil-binding protein (EBP) cause the Conradi-Hünermann-Happle syndrome. EBP was first identified as a binding target for the drug emopamil, a calcium-channel blocker. It was later found to be 3β-hydroxysteroid-δ8-δ7-isomerase that catalyzes an intermediate step in the conversion of lanosterol to cholesterol.[120] How this defect causes clinical manifestations is unclear.

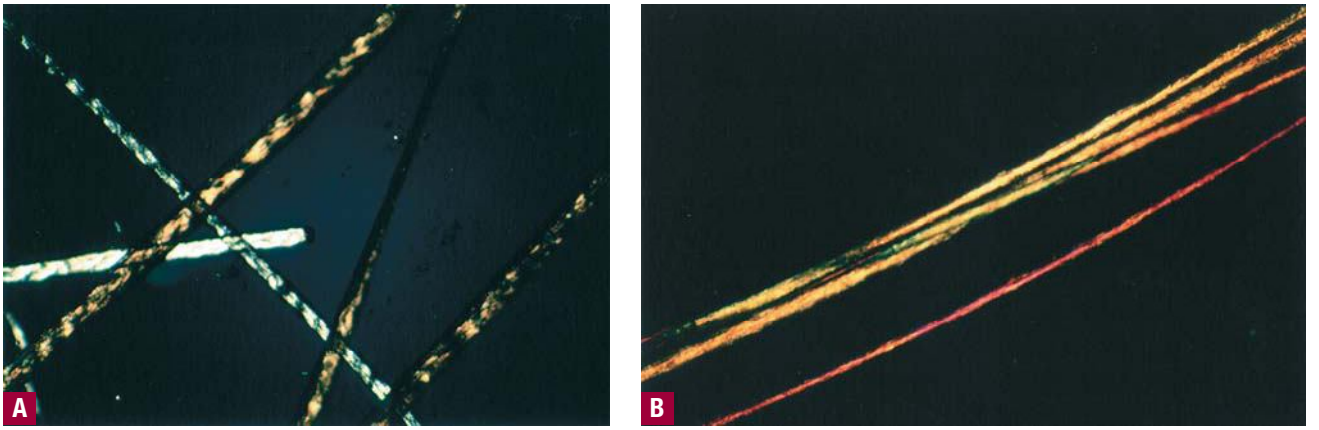
CHILD Syndrome

The CHILD syndrome (OMIM #308050) is a rare disorder that is found almost ex-



▲ **FIGURE 47-15** Trichothiodystrophy hair shows tiger-tail banding (**A**) under polarization, which is not observed with normal hair (**B**).

clusively in females.[121] The disorder is related to CDPX2 and also has skin and skeletal abnormalities. The ichthyosiform erythroderma has a psoriasiform morphology (see eFig. 47-14.1 in on-line edition) distinguished by a sharp midline demarcation with minimal linear or segmental contralateral involvement. Involvement of the right side occurs more frequently than the left. There may be bands of normal skin on the affected side. A case with bilateral involvement has been described. Limb defects occur ipsilateral to the ichthyosis and range from digital hypoplasia to agenesis of the extremity. There may be punctate calcification of cartilage. Unilateral hypoplasia can involve the central nervous system and cardiovascular, pulmonary, renal, endocrine, and genitourinary systems. The inheritance pattern is thought to be X-linked dominant, with the condition being lethal in males. Peroxisomal deficiency has been described in a study that showed fibroblasts from involved skin had fewer peroxisomes and accumulated cytoplasmic lipid; ultrastructurally, they accumulated lamellated membrane and vacuolar structures. Subsequently, mutations in either of two peroxisomal genes were found to cause CHILD syndrome. One patient was found to have a mutation in the gene encoding EBP (3β-hydroxysteroid-δ8-δ7-isomerase) (the gene underlying CDPX2)[122] and six patients (including one boy) were found to have mutations in NSDHL [*N*AD(P)H *s*teroid *deh*ydrogenase-*l*ike protein] encoding a 3β-hydroxysteroid dehydrogenase.[123] Each enzyme functions in the post-squalene cholesterol biosynthetic pathway, catalyzing intermediate steps in the conversion of lanosterol to cholesterol.[124]

Trichothiodystrophy

Trichothiodystrophy (TTD; OMIM #601675) is an autosomal recessive disorder that includes a broad spectrum of clinical phenotypes linked by the characteristic features of sulfur-deficient, brittle hair that exhibits tiger tail banding when viewed under polarizing microscopy (Fig. 47-15; see Chap. 140).[125] TTD hair shafts exhibit a variety of structural abnormalities related to a decrease in high sulfur matrix proteins and associated reduction in the ratio of strong to weak disulfide bonds within the hair shafts.[126–128] The disorder is reviewed in Chap. 140. Patients may have photosensitivity, ichthyosis, intellectual impairment, short stature, microcephaly, characteristic facial features (protruding ears, micrognathia) and decreased fertility.[125–130] The spectrum of clinical involvement is broad, ranging from only hair to severe multisystem abnormalities. Roughly one-half of TTD patients have clinical photosensitivity that ranges from subtle to severe. A similar number have ichthyosis, which also varies in severity from mild to severe. Newborns may have a collodion presentation, followed by decreasing erythema over weeks and evolution into a generalized ichthyosis, usually without erythema, which varies from fine, translucent scaling to large, dark yellow-brown hyperkeratosis (Fig 47-16B).[131,132] There may be flexural sparing, palmoplantar keratoderma, and dystrophic nails (ridging, splitting) (see Fig. 47-16A). Ectropion usually does not occur. There can be low birth weight, lack of subcutaneous fat (progeria-like facies), short stature, and delayed psychomotor development. Hypogonadism manifests as cryptorchidism in males and impaired sexual maturation in females.

A series of mnemonics have been used to describe the constellation of findings as BIDS (*b*rittle hair, *i*ntellectual impairment, *d*ecreased fertility, and *s*hort stature); when patients also have *i*chthyosis, IBIDS has been used; with the addition of *p*hotosensitivity, PIBI(D)S has been used.[133] However, these terms do not account for the other multisystem findings commonly present.

The majority of TTD patients have a defect in XPD (*ERCC2*). A few have mutations in XPB (*ERCC3*) or TTDA (*GTF2H5*), genes that are components of the transcription factor IIH (TFIIH) that regulates both DNA repair and transcription. Some TTD patients have mutations in *TTDN1*.[134] Although many TTD patients have photosensitivity, in contrast to xeroderma pigmentosum, these photosensitive patients have not been observed to be at high risk for the development of skin cancer. Nucleotide excision repair is one normal cellular mechanism by which structural DNA damage (e.g., ultraviolet-induced cyclobutane pyrimidine dimers) is removed and repaired (see Chaps. 109 and 140). TFIIH is involved in the initiation of transcription and also in nucleotide excision repair, and consists of a complex of proteins including the XPD and XPB proteins. In the vicinity of the damage, these two helicase subunits of TFIIH unwind the DNA in opposite directions.

Chanarin-Dorfman Syndrome

Chanarin-Dorfman syndrome (neutral lipid storage disease; OMIM #275630) is an autosomal recessive disorder characterized by accumulation of triglycerides in the cytoplasm of leukocytes, muscle, liver, fibroblasts, and other tissues. Blood lipid levels, however, are normal. To date, approximately 30 patients have been reported, mainly from the Mediterranean basin. The ichthyosis is a generalized fine scaling with variable erythema, resembling CIE. Presentation is often that of a collodion baby with ectropion and eclabium. Skin changes may evolve to orange-red with brown scale and are associated with pruritus. Extra-cutaneous involvement, which is vari-

▲ **FIGURE 47-16** Trichothiodystrophy. **A.** The nails are thinned and brittle, with onychoschizia, cracking, and irregular transverse depressions of the dorsal surface. **B.** Skin involvement in trichothiodystrophy can vary from absent to severe ichthyosis. This patient has a more severe ichthyotic involvement with dark-colored, adherent scale.

able and may be mild, includes cataracts, decreased hearing, hepatosplenomegaly with abnormal liver enzymes and fatty liver, psychomotor delay, myopathy with elevations in serum muscle enzymes, and neurologic abnormalities.

Multiple Sulfatase Deficiency

Multiple sulfatase deficiency (OMIM #272200) is a rare autosomal recessive disorder that is characterized by a deficiency of several sulfatases, which results in the accumulation of sulfatides, glycosaminoglycans, sphingolipids, and steroid sulfates in tissues and body fluids.[139] The activity of both lysosomal (arylsulfatases A and B) and microsomal (arylsulfatase C/steroid sulfatase of X-linked ichthyosis) arylsulfatases is impaired. The disorder is a composite of the clinical features of both metachromatic leukodystrophy and of a mucopolysaccharidosis.

Peeling Skin Syndrome

Peeling skin syndrome (OMIM #270300) is an autosomal recessive disorder characterized by lifelong peeling of the stratum corneum. It may be associated with pruritus, short stature, and easily removed anagen hairs. Low plasma tryptophan levels and aminoaciduria have also been reported.[143] Traupe suggested that there are two types of peeling skin syndromes.[5] Type A, which is noninflammatory and asymptomatic, is characterized by generalized peeling in thin superficial flakes of differing size and shape. In contrast, type B presents with congenital ichthyotic erythroderma and evolves into erythematous, scaling, migratory patches. This type is pruritic and may be associated with elevated levels of immunoglobulin E, aminoaciduria, and short stature. The stratum corneum is easily separated mechanically from the lower epidermis, and histologically the split, which occurs intercellularly, is seen between the stratum corneum and the granular layer.

Rud Syndrome

Rud syndrome (OMIM #308200) is a poorly characterized disorder, probably of recessive inheritance, that includes epilepsy, mental retardation, infantilism, congenital ichthyosis, and retinitis pigmentosa. Steroid sulfatase deficiency has been reported in some patients. Traupe critically reviewed the literature and suggested that the clinical constellation usually labeled Rud syndrome is associated with steroid sulfatase deficiency (X-linked recessive ichthyosis) and likely reflects a heterogenous group of disorders; because both the neurologic involvement and the ichthyosis are ill defined, the term *Rud syndrome* should be abandoned.[5]

ACQUIRED ICHTHYOSIS

The development of ichthyosis in adulthood can be a manifestation of systemic disease and has been described in association with malignancies, drugs, endocrine and metabolic disease, human immunodeficiency virus (HIV) and other infections, and autoimmune conditions.[149] The granular layer is often attenuated in this disorder, and the scale often resembles that seen in mild ichthyosis vulgaris. Although Hodgkin disease is the most common malignancy reported with acquired ichthyosis, non-Hodgkin lymphomas and a variety of other malignancies have also been observed.[150] Skin involvement may follow the course of malignancy and clear with effective cancer treatment. Acquired ichthyosis is commonly seen in association with acquired immunodeficiency syndrome; ichthyotic or xerotic skin has been observed in up to 30 percent of acquired immunodeficiency syndrome patients (see Chap. 198).[151] A study of HIV-1-positive intravenous drug users found acquired ichthyosis occurred only after profound helper T-cell depletion, more frequently with co-infection with human T-cell leukemia/lymphoma virus type 2, and suggested that it may be a marker for concomitant infection with HIV-1 and human T-cell leukemia/lymphoma virus type 2.[152]

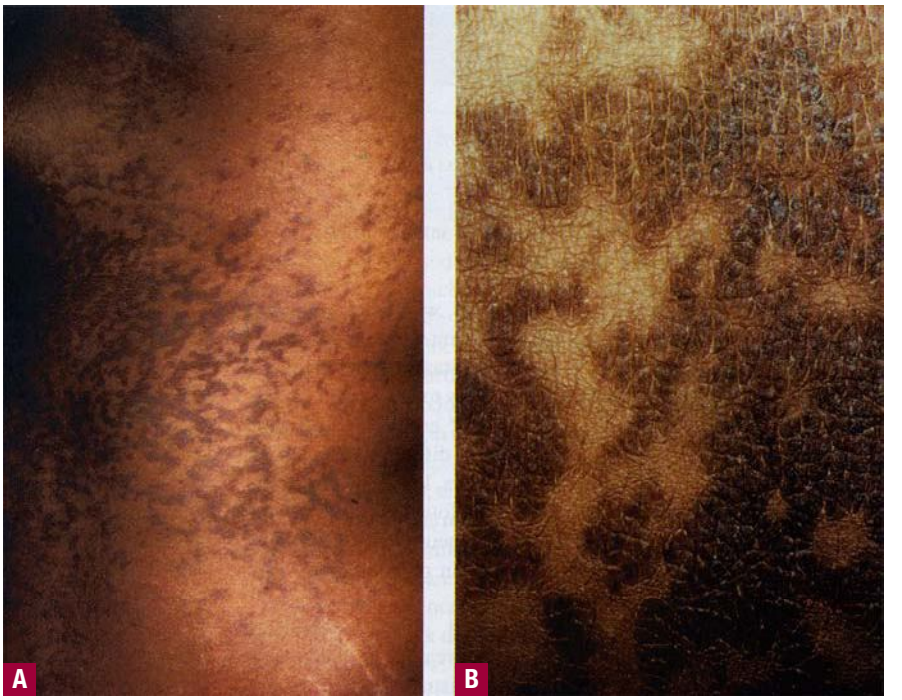
In acquired ichthyosis occurring in association with sarcoidosis, skin biopsy can be diagnostic, showing noncaseating granulomas in the dermis (see Chap. 153).[153] Acquired ichthyosis may be a marker of autoimmune disease, occurring with systemic lupus erythematosus, dermatomyositis, mixed connective tissue disease, and eosinophilic fasciitis (see Chaps. 30, 156, 157).[154,155] It has been described in bone marrow transplant recipients, where it may be related to graft-versus-host disease (see Chap. 28).[156]

Although occurrence in association with cholesterol-lowering agents (nico-

tinic acid, triparanol) highlights the relationship between cholesterol metabolism and normal desquamation, acquired ichthyosis has been observed with a variety of drugs, including butyrophenone (antipsychotic), dixyrazine (major tranquilizer), and nafoxidine (estrogen antagonist).[19] Kava is a psychoactive beverage made from the root of a pepper plant and used for thousands of years by Pacific Islanders. Heavy kava drinkers can acquire a reversible ichthyosiform eruption called *Kava dermopathy*. In Western nations, kava is sold in health food stores as a relaxant.[157]

Confluent and Reticulated Papillomatosis of Gougerot and Carteaud

Confluent and reticulated papillomatosis of Gougerot and Carteaud is an uncommon but distinctive acquired ichthyosiform dermatosis seen in young adults and characterized by persistent brown, scaly macules, papules, patches, and plaques. Lesions tend to be localized predominantly on the neck, upper trunk (intermammary and interscapular regions), and axillae where they tend to be confluent and become reticulated towards the periphery (Fig. 47-17). The lesions bear a clinical resemblance to tinea versicolor, a skin infection with *Pityrosporum* sp. A variety of treatment approaches have been reported, including topical (keratolytics, derivatives of vitamins A and D, antimicrobials) and systemic (antibiotics, retinoids) agents. Minocycline has been suggested as a first-line treatment; successful retreatment of recurrences supports the concept that this condition is an abnormal response to an infection or inflammation.[158,159]



▲ **FIGURE 47-17** Confluent and reticulated papillomatosis of Gougerot and Carteaud. **A.** Dark, scaly papules and plaques on the trunk, which become reticulated toward the periphery. **B.** Close-up view of the distinctive, scaly, reticulated papules and plaques. TREATMENT

Current therapies for the inherited ichthyoses are symptomatic and focus on hydration, lubrication, and keratolysis.[160,161] Ichthyotic skin, even if thickened, has a decreased barrier function and increased transepidermal water loss. Because pliability of the stratum corneum is a function of its water content, hydration can soften the surface of the skin. In moist, humid climates, most ichthyoses improve, and mild ichthyoses (e.g., ichthyosis vulgaris) may undergo extensive clearing. Moistening the skin with, for example, long baths can hydrate it. Well-hydrated areas of hyperkeratosis can more easily be thinned with mild abrasives (sponges, buff puffs, pumice stones, etc.). Addition of bath oils or application of lubricants before drying can prolong the hydration and softening. Depending on the ichthyosis and environmental conditions, individual patients may prefer specific lubricating agents, which can take the form of lotions, creams, oils, ointments, or petrolatum. In dry climates and winter months, humidifiers can be used to create a more hospitable environment.

Keratolytic agents are used to enhance corneocyte desquamation and thereby remove scale and thin hyperkeratotic stratum corneum. There are many commercially available keratolytic creams and lotions containing urea, salicylic acid, or α-hydroxy acids (e.g., lactic acid, glycolic acid). Urea may function by its capacity to bind water. Propylene glycol (40 percent to 60 percent in water), with or without occlusion, can also be effective in scale removal. Occlusion can effectively increase skin hydration and facilitate desquamation; it can also enhance the effect of keratolytic agents. Special care should be taken when using extensive areas of occlusion with keratolytic agents and in individuals who may be heat intolerant. Topical retinoid or vitamin D preparations may also be effective but can be irritating in some patients. The markedly impaired barrier function in ichthyosis should be considered when using topical preparations over large areas of body surface. For example, widespread use of topical salicylic acid preparations can lead to significant absorption, intoxication (e.g., nausea, tinnitus, dyspnea, hallucinations), and even death.[162] Children are at greater risk because they have a greater body surface area per unit weight than adults, a situation that effectively heightens the possibility of developing systemic toxicity from topicals. The abnormal skin barrier should be considered when treating concomitant dermatoses in ichthyosis patients. Topical 0.1 percent tacrolimus ointment is effective in atopic dermatitis with minimal systemic absorption. However, the atopic dermatitis of Netherton syndrome is complicated by a defective ichthyotic skin barrier. The defective barrier is associated with increased percutaneous absorption and risk for systemic toxic effects. This should be considered when using topical agents such as tacrolimus or topical steroids, where increased systemic absorption has been observed and monitoring of serum levels may be necessary.[85,86]

Another risk to children is that in several types of ichthyosis, nutritional requirements may be high, and inadequate

nutrition can lead to failure to thrive. This was thought to be related to the large turnover of scale; however, recent studies suggest energy loss from impaired barrier function is the cause.[163] Some patients with ichthyosis (particularly lamellar ichthyosis and CIE) have decreased sweating with heat intolerance. It is important for the parents of a newborn with ichthyosis to be aware of the possibility of decreased sweating and to be attentive for signs of heat intolerance, such as flushing and lethargy, particularly during hot weather, and, as the child grows, during exercise. Avoiding hot environments, carrying spray bottles with water to moisten the skin and cool it through evaporation, and cooling vests can minimize heat stress.

Systemic retinoid therapy with isotretinoin or acitretin can induce dramatic improvement in many ichthyoses and is particularly useful in lamellar ichthyosis, CIE, and erythrokeratodermia variabilis. The decision to initiate systemic retinoid therapy should be weighed carefully, because once the drug is started, continued benefit usually requires chronic therapy. Treatment of the harlequin newborn with systemic retinoid therapy during the newborn period can be lifesaving due to enhanced desquamation of a constricting membrane.

Fungal infections are common, both of skin and nails, and are often undiagnosed because of the generalized scaling. A high index of suspicion can help diagnose tinea corporis, capitis, or versicolor, where the only symptom may be localized pruritus and the only sign a difference in the character of scale or a localized area of alopecia.

The management of epidermolytic hyperkeratosis has acute and chronic aspects and varies with the clinical type. Areas of thick, hard hyperkeratosis, which are not pliable and have a hard rough surface, are prone to mechanical trauma. In patients with the hystrix type of porcupine-like hyperkeratosis, the rough surface causes high traction with objects moving across the skin surface, which tend to catch on the hyperkeratotic horn and peel it off. Topical agents such as lubricants and keratolytics can reduce the thickened, rough areas and help to minimize blistering and erosion. Bacterial infection of the skin is common, often leads to enhanced blistering, and may require frequent therapy with topical and oral antibiotics. In patients with extensive involvement, systemic retinoid therapy can be dramatically effective in decreasing the hyperkeratosis and the frequency of infections. Because these drugs can enhance blistering in epidermolytic hyperkeratosis patients, they should be administered carefully and started at low doses.

PRENATAL DIAGNOSIS

Molecular diagnosis is preferred when possible. Alternative methods, including fetoscopy and fetal skin biopsy, have the disadvantage of not being able to be performed early in pregnancy. Both harbor a risk of fetal mortality. For these and other reasons, fetal skin biopsy is rarely performed, and expert interpretation is almost impossible to obtain. In the past, fetal skin biopsy at approximately 20 to 22 weeks' gestation was performed in lamellar ichthyosis, CIE, epidermolytic hyperkeratosis, and SJS. In harlequin ichthyosis, prenatal diagnosis has been successfully performed by fetal skin biopsy[164] and ultrasonography.[165] When it is possible to do prenatal diagnosis by molecular analysis of a fetal sample, it is optimally performed early in pregnancy. This can be done with chorionic villous sampling or by amniocentesis in disorders where the underlying genetic defect is known, and the specific mutation in the family has been identified. If a specific mutation has not been identified, in some circumstances where there is an appropriate family structure, prenatal diagnosis can be done using linkage analysis. Prenatal diagnosis by mutational analysis has been accomplished in epidermolytic hyperkeratosis[166]; lamellar ichthyosis (*TGM1*); SJS (*FALDH*); ichthyosis bullosa of Siemens (*keratin 2*); PIBI(D)S (*ERCC2/XPD*, *ERCC3/XPB*); autosomal recessive RCDP(*PEX7*); X-linked chondrodysplasia punctata (arylsulfatase gene cluster at Xp22); Netherton syndrome (*SPINK-5*)[84]; and harlequin ichthyosis (*ABCA12*) (personal communication, David Kelsell, 7.26.06). In SJS, the diagnosis can be made by assay of enzyme activity in cultured amniocytes, even if the mutation in FALDH is undefined. For autosomal recessive disorders where the mutation is known (e.g., lamellar ichthyosis and SJS), carrier detection may be performed for at-risk relatives.

See Box 47-1 for more information on the ichthyoses.

CHAPTER 48

Inherited Keratodermas of Palms and Soles

David P. Kelsell
Irene M. Leigh

EPIDEMIOLOGY

All these conditions are rare.

ETIOLOGY AND PATHOGENESIS

Palmoplantar keratodermas (PPKs) are a heterogeneous group of disorders characterized by abnormal thickening of the palms and soles.[1] Autosomal recessive, X-linked, and dominant modes of inheritance as well as acquired forms have all been described. The palmoplantar epidermis is a specialized epidermis. Many of the PPKs arise due to inherited gene defects encoding the structural components of the keratinocyte.[2] The most abundant proteins of the keratinocyte are the keratins, of which eight keratin genes are mutated in a wide spectrum of the keratodermas.[3] The keratin intermediate filaments (IFs) are attached at the plasma membrane to the main cell junction of the epidermis, the desmosome. Desmosomal proteins mutated in the keratodermas include desmoplakin, plakoglobin, plakophilin, and desmosomal cadherins (see Chap. 44).[4] Mutations in other junctional proteins of the adherens junction and gap junctions are also implicated in these skin diseases. These three cell junction types have key roles in keratinocyte adhesion and cell–cell communication.

Although many of the structural proteins found in the palmoplantar epidermis are not palmoplantar-specific, others, such as keratin 9 (K9), are unique to this site. K6a and K16 are found in the palmoplantar epidermis, nail plate, hair follicle, oral mucosa, sweat gland, and larynx, but not in normal skin. Thus, abnormalities of these keratins are likely to be distributed clinically in these sites. K17 has a limited basal expression in the palmoplantar epidermis but is extensively expressed in the outer hair root sheath and the nails; abnormalities of this keratin are likely in these sites. Mutations in the keratin genes lead to an unstable filament network. The codistribution of certain structural proteins with other tissues (for example, muscle, nerve, and brain) may explain some genetic diseases associated with multiple organ involvement, such as desmoplakin and plakoglobin mutations with cardiocutaneous syndromes and connexin mutations associated with PPK, deafness, and neuropathy.

Desmoplakin is the most abundant of the desmosomal proteins and attaches the IF network, particularly the type II keratins, to the cell membrane. It also binds other desmosomal proteins such as plakoglobin and plakophilin. Desmoplakin is linked to the desmosomal cadherins (the desmocollins and desmogleins) indirectly via the binding of plakoglobin and plakophilin. The desmogleins and desmocollins are the cell–cell adhesive proteins of the desmosome. Plakoglobin is also a component of adherens junctions that bind actin filaments rather than IFs (see Chap. 51).

Connexins are the major protein components of the gap junction. Four connexins are implicated in skin diseases, often in syndromic forms associated with hearing loss or neuropathy.[5,6] Gap junctions, formed from aqueous connexin channels, facilitate intercellular communication, allowing the exchange of small molecules between cells. This, in turn, leads to coordination within the tissue, mediating differentiation and response to cellular damage.

Non-structural proteins are also involved in the pathogenesis of the kerato-

INHERITED KERATODERMAS OF PALMS AND SOLES AT A GLANCE

- Palmoplantar keratodermas form a rare but highly diverse group of hereditary skin disorders.
- Chronic thickening of palms and soles may be found alone (simple), in combination with skin lesions elsewhere (complex), or in association with complex syndromes (syndromic), including ectodermal dysplasia where hair, teeth, and nails may be affected.
- Examination will subclassify keratodermas according to whether they affect the whole palm and sole (diffuse), or are restricted to more limited areas (focal) or bead-like tiny lesions (punctate).
- Complications include severe pain, difficulty in walking, and secondary infection.
- The genetic basis of many keratodermas particularly involves mutations in genes encoding keratins, connexins, and desmosomal components.
- Associated cardiomyopathies, deafness, cancer, musculoskeletal and neurologic disorders can, in part, be explained by the underlying biology and tissue expression of affected genes.
- Treatments target removal of hyperkeratotic material by keratolytics and systemic retinoids; appropriate footwear is helpful.

dermas, including the SLURP1 protein, which is secreted and involved in cell signaling and adhesion. A metabolic defect in tyrosine aminotransferase leading to increased serum tyrosine and phenolic acid metabolites also results in keratoderma. Table 48-1 provides an overview of the different keratodermas, their mode of inheritance, and underlying gene defects discussed in this chapter.

CLINICAL FINDINGS

General

Three distinct clinical patterns of PPK may be identified:

- *Diffuse PPK*, which is characterized by an even, thick, symmetric hyperkeratosis over the whole of the palm and sole. This pattern is usually evident at birth or in the first few months of life.
- *Focal PPK*, in which large, compact masses of keratin develop at sites of recurrent friction, principally on the feet, although also on the palms and other sites. The pattern of calluses in this focal group may be either discoid (nummular) or linear.
- *Punctate PPK*, in which multiple tiny "raindrop" keratoses involve the palmoplantar surface. They may involve the whole of the palmoplantar surface or may be more restricted in their distribution (i.e., palmar creases).

Considerable intra- and interfamily variation is often seen. Historically, emphasis in clinical diagnosis has been placed on the extent of spread (transgrediens) of the keratoderma onto the wrists, dorsa of the hands, knuckles, elbows, and knees. However, transgrediens is a highly variable feature, even within the same family, and probably represents little more than the normal variation in the extent of ridged skin in that particular patient. Similarly, the progression with age (progrediens) is unhelpful because many of the keratodermas are induced by physical trauma; thus the severity of the keratoderma may reflect the physical activity and weight of that patient.

The keratodermas can additionally be classified into three further subgroups

- *Simple* keratodermas with only PPK
- *Complex* keratodermas with PPK associated with lesions of nonvolar skin, hair, teeth, nails, and/or sweat glands, including the ectodermal dysplasias
- *Syndromic* keratodermas with PPK associated with abnormalities of other organs, including deafness, cardiomyopathy, and cancer

TABLE 48-1
Genes in Palmoplantar Keratoderma (PPK)

Keratoderma Type	Mode of Inheritance	Underlying Gene Defect
EPPK	AD	K9/K1
Pachyonychia congenital types I and II	AD	K6a, K6b, K16, and K17
Ichthyosis hystrix	AD	K1
Vohwinkel syndrome	AD	Cx26
KID syndrome	AD	Cx26/Cx30
PPK and hearing loss	AD	Cx26
EKV	AD/AR	Cx31/Cx30.3
HED	AD	Cx30
Bart-Pumphrey syndrome (hearing loss, PPK, knuckle pads, and leukonychia)	AD	Cx26
Oculo-dento-digital dysplasia (development of the face, eyes, skeletal system, heart, and dentition, plus keratoderma)	AD	Cx43
Diffuse NEPPK	AD	12q11-q13 or Desmoglein 1
Striate keratoderma	AD	Desmoplakin, Desmoglein 1, or K1
Skin fragility-ectodermal dysplasia syndrome	AR	Plakophilin 1
SPPK or EPPK, woolly hair/cardiomyopathy	AD/AR	Desmoplakin
Lethal acantholytic epidermolysis bullosa	AR	Desmoplakin
NEPPK, woolly hair, and ARVC (Naxos disease)	AR	Plakoglobin
Papillon-Lefèvre/Haim-Munk syndrome	AR	Cathepsin C
Mal de Meleda	AR	Slurp1
Camisa disease (honeycomb palmoplantar keratoderma with ichthyosis)	AD	Loricrin
CEDNIK syndrome	AR	SNAP29 (vesicle fusion)
Oculocutaneous tyrosinemia	AR	Tyrosine aminotransferase
NEPPK and sensorineural deafness		Mitochondrial (A7445G)
Huriez syndrome	AD	4q23
KLICK syndrome	AR	13q
Punctate PPK	AD	15q22.2–15q22.31
Focal PPK with esophageal cancer	AD	17q25

AD = autosomal dominant; AR = autosomal recessive; ARVC = arrhythmogenic right ventricular cardiomyopathy; CEDNIK = *ce*rebral *d*ysgenesis, *n*europathy, *i*chthyosis, and *k*eratoderma; Cx = connexin; EPPK = epidermolytic palmoplantar keratoderma; EKV = erythrokeratodermia variabilis; HED = hidrotic ectodermal dysplasia; K1 etc. = keratin 1; KID = keratitis, ichthyosis, and deafness; KLICK = *k*eratosis *l*inearis with *i*chthyosis *c*ongenita and sclerosing *k*eratoderma; NEPPK = nonepidermolytic palmoplantar keratoderma; Slurp1 = secreted LY6/PLAUR domain containing 1; SNAP29 = synaptosomal-associated protein 29; SPPK = striate palmoplantar keratoderma.

DIFFUSE PALMOPLANTAR KERATODERMA

Diffuse Epidermolytic PPK [PPK Cum Degeneratione Granulosa Vörner, Vörner's Epidermolytic Palmoplantar Keratoderma (Simple)]. Diffuse epidermolytic PPK is one of the most common patterns of PPK. It is an autosomal dominant condition that presents within the first few months of life. The keratoderma presents as a well-demarcated, symmetric thickening of palms and soles and often has a "dirty" snakeskin appearance due to the underlying epidermolysis that produces a very characteristic fissuring

▲ **FIGURE 48-1** Diffuse epidermolytic palmoplantar keratoderma. A "dirty" keratoderma involving the entire palmar surface is demonstrated. (Used with permission from Barts and the London NHS Trust, United Kingdom.)

(Fig. 48-1). Knuckle pads have been reported rarely, and there may be minimal involvement of the elbows and knees.

Diffuse Nonepidermolytic PPK [Unna-Thost Disease, Diffuse Orthohyperkeratotic Keratoderma, Tylosis, Keratosis Palmoplantaris Diffusa Circumscripta, Keratosis Extremitatum Progrediens (Simple)]. Diffuse nonepidermolytic PPK is inherited as an autosomal dominant condition and is present from infancy. Clinically, there is a well-demarcated, symmetric, often "waxy" keratoderma involving the whole of the palms and soles (Fig. 48-2) with a sharp cutoff at the wrist. Spread of the hyperkeratosis to the dorsa of the hands and wrists is a variable feature within most pedigrees but a "cobblestone" hyperkeratosis of the knuckles may be seen. The dorsa of the fingers are often involved, with a scleroderma-like thickening of the skin distal to the proximal interphalangeal joint. Elbows and knees are rarely involved "Parrot beaking" of the fingernails and widening of the onychocorneal band are characteristic. Secondary dermatophyte infection, leading to maceration and peeling of the palms and soles, is a common complication. It is of note that re-examination of the histology of the index family of Unna-Thost disease, has shown that this family had epidermolytic PPK rather than nonepidermolytic.

▲ **FIGURE 48-2** Diffuse nonepidermolytic palmoplantar keratoderma. Note the waxy keratoderma involving the entire plantar surface with involvement of the non–weight-bearing digits. (Used with permission from Barts and the London NHS Trust, United Kingdom.)

Huriez Syndrome [PPK with Sclerodactyly, Scleroatrophic and Keratotic Dermatosis of Limbs, Sclerotylosis (Syndromic)]. Huriez syndrome is an autosomal dominant keratoderma with sclerodactyly that presents from birth with a diffuse symmetric keratoderma of the palms and soles. The fingers have a pseudoscleroderma tous appearance. Atrophic fibrosis of limb skin also may be seen. Variable nail features have been described, with longitudinal ridging hypoplasia and clubbing. Squamous cell carcinoma develops in the atrophic skin in the third to fourth decades, and bowel cancer also has been described in association with this phenotype.

Mal de Meleda [Mutilating PPK of the Gamborg-Nielsen Type, Acral Keratoderma, Palmoplantar Ectodermal Dysplasia Type VIII (Complex)]. Mal de Meleda is an autosomal recessive keratoderma that presents at birth or in early infancy. The keratoderma is diffuse, symmetrically involving the palms and soles with spread to the dorsa of the hands in a glove-and-stocking distribution. Knuckle pads with elbow and knee hyperkeratosis have been described. Constricting bands (pseudoainhum) around the digits may develop (see Chap. 66), resulting in loss of function and autoamputation of digits. Koilonychia, subungual hyperkeratosis, longitudinal grooving, onychogryphosis, and leukokeratosis also have been described. Other associations include angular cheilitis, hyperhidrosis, and poor physical development with electroencephalographic anomalies and brachydactyly.

PPK of Sybert [Greither Palmoplantar Keratoderma, Keratosis Palmoplantaris Transgrediens et Progrediens, Keratosis Extremitatum Hereditaria Progrediens (Complex)]. PPK of Sybert is an extremely rare autosomal dominant keratoderma with symmetric severe involvement of the whole palmoplantar surface in a glove-and-stocking distribution. Spread of the keratoderma involves elbows and knees. Pseudoainhum formation with amputation of the digits has been described.

Olmsted Syndrome [Mutilating Palmoplantar Keratoderma with Periorificial Keratotic Plaques, Polykeratosis of Touraine (Syndromic)]. With the exception of one family in which a mother and son were affected, suggesting autosomal dominant transmission, all cases of Olmsted syndrome appear to be sporadic. Diffuse mutilating keratoderma of the palms and soles with flexion deformity of the digits begins in infancy. Constricting bands around the digits lead to autoamputation of the digits. There are progressive perioral, perianal, and perineal hyperkeratotic plaques that may extend to the inner thigh and groin. Alopecia, deafness, nail dystrophy, and dental loss have all been reported. Corneal epithelial dysplasia, leading to corneal scarring and visual impairment, has been reported in one patient, and leukokeratosis has been reported in two patients. Acrodermatitis enteropathica needs to be excluded by measurement of serum zinc levels.

Congenital Poikiloderma with Traumatic Bulla Formation, Anhidrosis, and Keratoderma [Naegeli-Franceschetti-Jadassohn Syndrome (Complex)]. Congenital poikiloderma with traumatic bulla formation, anhidrosis, and keratoderma is an autosomal dominant condition, with onset within the first few years of life, which presents with reticulate pigmentation that may be extensive and not preceded by any inflammation. The pigmentation particularly involves the neck and axilla. A diffuse keratoderma with punctiform and linear accentuations is usually seen, and adermatoglyphia occurs. The hair is normal, but variable nail changes have been described, from almond nails to onychodystrophy. The teeth have enamel defects, are abnormally shaped, and are lost early. Hypohidrosis or anhidrosis is the principal problem, leading to heat intolerance. Because this disorder was considered initially to be a noninflammatory variant of incontinentia pigmenti, transitional cases between the two syndromes have been described.

▲ **FIGURE 48-3** Striate keratoderma. Linear calluses extend up the fingers; this phenotype is highly variable even within the same family. (Used with permission from Barts and the London NHS Trust, United Kingdom.)

FOCAL PALMOPLANTAR KERATODERMA

Striate PPK [Brünauer-Fuhs-Siemens Type, Keratosis Palmoplantaris Varians, Wachters PPK, Acral Keratoderma (Simple)]. Striate PPK is an autosomal dominant keratoderma that principally involves the soles with onset in infancy or the first few years of life. The hands may show minimal callous formation; however, with manual labor, a striate pattern of PPK is seen over the palmar aspects of the digits (Fig. 48-3). Elbow and knee involvement is seen variably. Patients also report increased skin fragility, with the skin splitting following trauma, but blistering does not occur. Nails and hair may be variably involved, with ridging of the nails and cuticular hyperkeratosis; woolly hair has been reported in a few individuals.

Pachyonychia Congenita Type I [Jadassohn-Lewandowsky Syndrome (Complex)]. Pachyonychia congenita type I is an autosomal dominant keratoderma that principally involves the plantar surfaces (Fig. 48-4). Onset of plantar calluses may be delayed up to 7 years of age. Nail changes may be evident at birth but more commonly develop within the first few months of life. They are characterized by an upward angulation of the distal end of the nail as a result of subungual hyperkeratosis, giving the characteristic "door wedge" distal hyperkeratosis (see eFig. 48-4.1 in on-line edition; see Chap. 87).[6] Calluses develop over the plantar pressure points (see Fig. 48-4); palmar calluses are not seen except in manual workers. Blistering may occur on walking. Hair abnormalities and oral, laryngeal, and follicular hyperkeratosis have all been described.

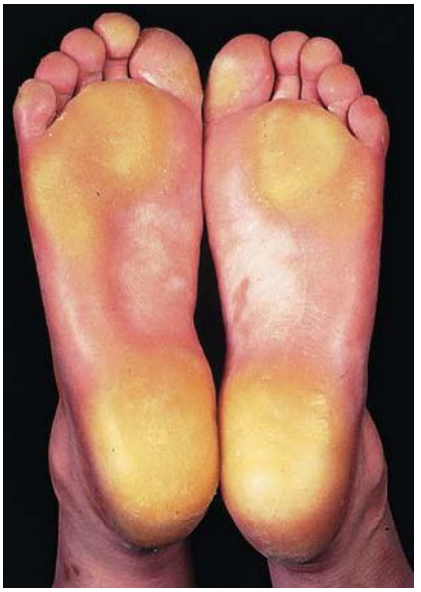
Focal Palmoplantar Keratoderma with Oral Mucosal Hyperkeratosis [Keratosis Palmoplantaris Nummularis, Hereditary Painful Callosity Syndrome, Keratosis Follicularis (Complex)]. Focal PPK with oral mucosal hyperkeratosis represents a clinical overlap syndrome with pachyonychia congenita type I but without the classic nail involvement. It is an autosomal dominant keratoderma in which calluses develop over plantar pressure points. Sparing of palms occurs except in manual workers. Oral hyperkeratosis is seen, particularly involving the labial attached gingiva. The follicular hyperkeratosis evident over the arms and legs becomes less prominent with age. Nail changes range from widening of the onychocorneal band with splinter hemorrhages to the door-wedge subungual hyperkeratosis characteristic of pachyonychia type I. Blistering may occur on walking, thus limiting physical activity. Epidermolysis is a variable feature.

▲ **FIGURE 48-4** Pachyonychia congenita type I. This figure demonstrates a focal palmoplantar keratoderma involving most of the plantar surface but with sparing of the non–weight-bearing digits. (Used with permission from Barts and the London NHS Trust, United Kingdom.)

Pachyonychia Congenita Type II [Jackson-Sertoli Syndrome, Jackson-Lawler Pachyonychia Congenita (Complex)]. Pachyonychia congenita type II is an autosomal dominant keratoderma presenting with a limited focal plantar keratoderma that may be very minor. Nail changes may be evident at birth but more commonly develop within the first few months of life. The nail changes are characterized by an upward angulation of the distal end of the nail as a result of subungual hyperkeratosis to give the characteristic door-wedge distal hyperkeratosis. Multiple epidermal cysts and steatocystoma are seen. All individuals have woolly scalp hair, and the eyebrows grow straight out, giving a bushy appearance. Natal teeth are seen variably.

Papillon-Lefèvre Syndrome (Syndromic). Papillon-Lefèvre syndrome is an autosomal recessive disease that develops within the first few months of life. The pattern is focal and involves most of the palmoplantar surface with punctiform accentuation in some areas, particularly along the palmoplantar creases (Fig. 48-5). Spread of the keratoderma to the dorsa of the hands and to the Achilles tendons, elbows, and knees is found in some cases. Severe periodontitis occurs following

▲ **FIGURE 48-5** Papillon-Lefèvre syndrome. A complex pattern of keratoderma with focal and punctate lesions involving the sole is demonstrated. (Used with permission from Barts and the London NHS Trust, United Kingdom.)



▲ **FIGURE 48-6** Palmoplantar keratoderma associated with esophageal malignancy. Note the focal palmoplantar keratoderma involving most of the plantar surface but with sparing of the non–weight-bearing digits. (Used with permission from Barts and the London NHS Trust, United Kingdom.)

eruption of deciduous dentition and recurs with permanent dentition. A subtle, generalized, whitish opalescence of the oral mucosa has been described. Transverse ridging of nails, onychogryphosis, and sheeted follicular hyperkeratosis have all been described. A proneness to infections also has been reported.

Palmoplantar Keratoderma Associated with Esophageal Cancer [Palmoplantar Ectodermal Dysplasia Type III, Tylosis (Syndromic)]. PPK associated with esophageal cancer is an autosomal dominant keratoderma that occurs with late onset. The keratoderma principally is of the focal type involving the plantar pressure points. More diffuse patterns may be seen in some patients, but the non–weight-bearing digits are always spared (Fig. 48-6). The age of onset is usually between 7 and 8 years of age. The palms are usually not involved, but there may be callus formation in manual workers. Oral leukokeratosis often predates the onset of the PPK and involves the buccal mucosa more than the labial attached gingival mucosa. Widespread follicular hyperkeratosis is evident, particularly in children. The nails are normal, and this is an important differentiating feature from focal PPK with oral hyperkeratosis. Associated features: the risk of developing esophageal squamous cell carcinoma in these families has been reported as between 40 percent and 90 percent of those affected by age 65. Oral squamous cell carcinomas also have been reported, and there may be an increased incidence of other tumors.

Oculocutaneous Tyrosinemia [Tyrosinemia Type II, Richer-Hanhart Syndrome (Syndromic)]. (See Chap. 131) Oculocutaneous tyrosinemia is an autosomal recessive condition, with onset between ages 2 and 4 years when painful, circumscribed callosities develop on the pressure points of the palm and sole. Occasionally, calluses also may develop on the elbows and knees. Photophobia and corneal erosions develop within the first few months of life. The corneal erosions may progress to corneal ulceration and glaucoma. Mental retardation develops if patients are not treated. When patients are placed on a low-tyrosine, low-phenylalanine diet, the cutaneous and ocular manifestations disappear.

Vohwinkel Syndrome [Keratoma Hereditarium Mutilans (Syndromic)]. Vohwinkel syndrome is an autosomal dominant keratoderma with onset in early infancy that presents with a honeycombed keratoderma involving the palmoplantar surfaces. Flexion contractures and constricting bands of digits, particularly of the fifth digit, result in autoamputation (Fig. 48-7). Spread of the keratoderma occurs with linear and/or starfish keratoses on the extensor surfaces of the elbows, knees, and knuckles. Mild to moderate sensorineural hearing loss is often associated. A diffuse, generalized ichthyosiform dermatosis may be seen in some affected individuals and is specific to the form associated with normal hearing, which is due to loricrin mutations. Nail dystrophy, alopecia, onychogryphosis, and a variety of neurologic abnormalities other than sensorineural hearing loss, such as spastic paraplegia and myopathy, have been described.

PUNCTATE PALMOPLANTAR KERATODERMA

Keratosis Punctata Palmaris et Plantaris [Buschke-Fischer-Brauer Disease, Keratosis Papulosa, Papulotranslucent Acrokeratoderma, Keratoderma Punctatum, Maculosa Disseminata, Davis Colley Disease (Simple)]. Keratosis punctata palmaris et plantaris is an autosomal dominant PPK

◀ **FIGURE 48-7** Vohwinkel syndrome. **A.** Note the diffuse pattern of keratoderma with pseudoainhum formation and (**B**) autoamputation of fifth digits. Note also starfish keratoses on knuckles (**A**). (Used with permission from Department of Dermatology, University of Heidelberg, Germany.)

▲ **FIGURE 48-8** Punctate keratoderma of palms (**A**) and soles (**B**).

with variable penetrance that develops at 12 to 30 years of age. Clinically, there are multiple, tiny, punctate keratoses over the entire palmoplantar surfaces, but they begin over the lateral edge of the digits (Fig. 48-8). Lesions are induced by physical trauma and made worse by paring and/or chiropody. The punctate keratoses coalesce into a more diffuse pattern over the pressure points of the sole. Variable nail changes have been described but are an inconsistent part of the phenotype. An association with diverse malignancies in a few families is likely to have occurred by chance.

Spiny Keratoderma [Punctate Keratoderma, Punctate Porokeratosis of the Palms and Soles, Porokeratosis Punctata Palmaris et Plantaris (Complex)]. Spiny keratoderma is an autosomal dominant keratoderma of late onset that develops in patients aged 12 to 50 years. Multiple tiny keratotic plugs, mimicking the spines on a music box, involve the entire palmoplantar surfaces. It may be associated with facial sebaceous hyperplasia.

Focal Acral Hyperkeratosis [Acrokeratoelastoidosis Lichenoides, Degenerative Collagenous Plaques of the Hands (Simple)]. Focal acral hyperkeratosis is a late-onset keratoderma, inherited as an autosomal dominant condition, that presents with oval or polygonal crateriform papules developing along the border of the hands, feet, and wrists. These concentrate in skin creases but occasionally a more confluent pattern is seen over the palms or soles to give a diffuse pattern. The disease is principally found in black races. Elastorrhexis has been reported but is probably not a characteristic feature.

ECTODERMAL DYSPLASIAS AND ERYTHROKERATODERMAS ***Hidrotic Ectodermal Dysplasia [Fischer-Jacobsen-Clouston Syndrome, Alopecia Congenita with Keratosis Palmoplantaris, Keratosis Palmaris with Drumstick Fingers, PPK and Clubbing (Complex)].*** This entity is discussed in Chap. 143.

Erythrokeratodermia Variabilis [Progressive Symmetric Erythrokeratoderma, Keratosis Palmoplantaris Transgrediens et Progrediens, Keratosis Extremitatum Progrediens (Complex)]. (See Chap. 47) Erythrokeratodermia variabilis is a keratoderma that is usually inherited in an autosomal dominant fashion, although recessive cases have been reported. The PPK is evident in infancy and increases in severity throughout childhood. Sharply outlined geographic areas of erythrokeratoderma are distributed symmetrically over the body. Erythematous desquamation of the palms and soles with hyperhidrosis is characteristic, but the disease is not palmoplantar-specific. Spread of the keratoderma to the dorsa of the hands and feet is seen commonly. Associated defects are rare in erythrokeratodermia variabilis; however, neurologic anomalies (deafness, peripheral neuropathy, decreased tendon reflexes, nystagmus, dysarthria, and cerebellar ataxia) and onychodystrophy have been described.

KERATODERMAS AND ASSOCIATED SYNDROMES ***Diffuse Palmoplantar Keratoderma, Woolly Hair and Arrhythmogenic Right Ventricular Cardiomyopathy [Naxos Disease (Syndromic)].*** Both recessive and dominant conditions of diffuse PPK have been described. The recessive disorder (Naxos disease) has a clear association with cardiomyopathy. The disorder is characterized by the development, during infancy, of a diffuse keratoderma over the plantar pressure points. Other cutaneous anomalies include acanthosis nigricans of the axilla and groin, diffuse xerosis, follicular hyperkeratosis over the zygoma, and palmoplantar hyperhidrosis. Woolly hair over the scalp and short, scanty eyebrows, eyelashes, beard, and axillary and pubic hair are seen. Nails, teeth, and sweat gland function are all normal. Endomyocardial fibrodysplasia with ventricular tachycardia and right ventricular dilatation with right ventricular bands have been reported.

Striate Palmoplantar Keratoderma, Woolly Hair and Left Ventricular Dilated Cardiomyopathy [Carvajal Syndrome (Syndromic)]. Both dominant and recessive forms of striate PPK, woolly hair, and left ventricular dilated cardiomyopathy have been described, with a clear association with cardiomyopathy. The skin disease presents as a striate PPK with some non-volar involvement, particularly at sites of pressure or abrasion. Cardiologic investigation of a number of affected family members with the recessive form has been reported, with the diagnosis of a left ventricular dilated cardiomyopathy, often resulting in heart failure during adolescence. Cardiac manifestations are variable, with some cases having arrhythmogenic right ventricular cardiomyopathy or both ventricles involved.

Keratitis, Ichthyosis, and Deafness Syndrome [Ichthyosiform Erythroderma, Corneal Involvement, and Deafness; Desmons Syndrome (Syndromic)]. (See Chap. 47) Keratitis, ichthyosis, and deafness syndrome is an autosomal dominant disorder with profound sensorineural deafness that presents from birth. Ichthyosiform erythroderma develops with a well-marginated serpiginous outline. Follicular hyperkeratosis, perioral furrowed plaques, and oral leukokeratosis have been described. Other changes include a diffuse keratoderma with a reticulate surface, recurrent infections, sensorineural deafness, keratoconjunctivitis and photophobia, hepatitis, mental retardation, and skeletal abnormalities with short stature and pes cavus. Hypotrichosis and nail dystrophy may occur. Multiple cutaneous squamous cell carcinomas are seen.

Palmoplantar Keratoderma and Spastic Paraplegia [Charcot-Marie-Tooth Disease with PPK and Nail Dystrophy (Syndromic)]. PPK and spastic paraplegia is an autosomal dominant or X-linked dominant keratoderma that begins in early childhood with a thick focal keratoderma over the soles and, to a lesser extent, the palms. Punctate keratoderma has been described

in one family. Pes cavus, frontal balding, spastic paraplegia (motor and sensory neuropathy), and mental retardation are reported. Muscular atrophy that develops at approximately 40 years of age starts in the lower legs, with weakness, progressive gait difficulties, and stumbling. Nail dystrophy is an inconsistent feature.

Eyelid Cysts, Palmoplantar Keratosis, Hypodontia, and Hypotrichosis [Schöpf-Schulz-Passarge Syndrome (Syndromic)]. Eyelid cysts, palmoplantar keratosis, hypodontia, and hypotrichosis is an autosomal recessive condition with diffuse symmetric PPK. PPK and fragility of the nails begin around age 12 years. Hair becomes sparse by age 25, and cysts of the eyelid margins occur at age 60. Other changes include facial telangiectasia, early loss of teeth, generalized hypotrichosis, and longitudinal and oblique furrows in nails. Multiple squamous cell carcinomas in the area of the PPK are reported, as well as eccrine poromas, hypernephroma, and basal cell carcinoma. Apocrine hidrocystoma of the eyelid margins is one manifestation.

HISTOPATHOLOGY

1. Epidermolytic hyperkeratosis (EHK) is found in epidermolytic PPK and other diseases characterized by keratin mutations with keratoderma [such as bullous ichthyosiform erythroderma (see Chap. 47) and the Dowling-Meara form of epidermolysis bullosa simplex (see Chap. 60)], including pachyonychia congenita type I. EHK is characterized by marked hyperkeratosis, acanthosis, and papillomatosis. The keratinocytes throughout the spinous and granular cell layers show epidermolysis at light microscopic level, with keratin aggregates and cytolysis seen readily by electron microscopy. Because epidermolysis is easily missed if the biopsy is performed from the edge of the palm or sole, it is important to biopsy a weight-bearing area or the thenar or hypothenar eminence. In pachyonychia congenital type II, keratin filament aggregation is restricted in the nonvolar epidermis to sites of keratin K17 and K6b expression, particularly the deep outer hair root sheath and ducts of the sebaceous glands. The exact histology of the cysts seen in both pachyonychia congenita type II and steatocystoma multiplex depends on the part of the pilosebaceous unit involved. Most consist of vellus hair cysts, but epidermal cysts, keratin-filled cysts, and steatocysts also may be seen.
2. Striate keratodermas. The skin lesions are often but not always characterized by filament aggregates close to the cell membrane with widened intercellular spaces and attenuated desmosomal connections.
3. Non-specific changes. Many keratodermas are difficult to distinguish histologically in the absence of epidermolytic change, and a clear differential diagnosis is difficult. Generally, non-epidermolytic keratodermas show orthohyperkeratosis and acanthosis, with a well-preserved granular cell layer. There are a number of subtle distinguishing features in some keratodermas.
   i. Erythrokeratodermas: Electron microscopy shows abnormalities in the stratum granulosum, where a prominent tonofilament-keratohyalin complex envelops a clear cytoplasmic halo around an often crenelated nucleus.
   ii. PPK of Sybert: In involved skin, lipid-laden cells accumulate in the stratum corneum, giving the cells a clear, punctate profile. Amyloid deposition has been noted in the superficial zone of the papillary dermis after treatment with retinoids.
   iii. Naegeli-Franceschetti-Jadassohn syndrome: Typically shows patchy hyperpigmentation of the epidermis and marked secondary pigmentary incontinence, with numerous melanophages, containing melanin granules, in the upper dermis. Eccrine glands appear normal in size and number.
   iv. Papillon-Lefèvre syndrome: The skin lesions show hyperkeratosis with occasional parakeratotic patches, acanthosis, and slight perivascular infiltrates. The periodontal lesions are characterized by pocket formation, with secondary ulceration of the pocket epithelium and a mixed inflammatory cell infiltrate.
   v. Oculocutaneous tyrosinemia: Histology of the palmoplantar lesions may be helpful diagnostically in demonstrating eosinophilic cytoplasmic inclusions.
   vi. Vohwinkel disease: Histopathology demonstrates the characteristic feature of hyperkeratosis with "round" retained nuclei with hypergranulosis.
   vii. Punctate porokeratosis: Histology shows columnar parakeratosis, which resembles the cornoid lamella of porokeratosis, with a poorly developed granular cell layer.

DIFFERENTIAL DIAGNOSIS

The diagnosis is initially made on the clinical distribution of lesions, associated features, and the presence of a family history. Histopathology is helpful to confirm the presence of EHK and to exclude other possible diagnoses, particularly in late onset cases. However, the majority of disease phenotypes are present at birth or in early life and therefore, the presence of a genetically determined disease should be the primary consideration. Knowledge of the molecular basis of these diseases can now lead to the screening of candidate genes as an aid to diagnosis. These genetic tests can be provided by commercial, academic, or health service organizations (see Table 48-1).

Most likely differential diagnoses in late-onset PPKs are shown in Box 48-1.

COMPLICATIONS OF KERATODERMAS

- Pain: This is a particular problem in focal keratodermas with accentuation of lesions on the weight-bearing areas, such as pachyonychia congen-

Box 48-1

Differential Diagnosis of Late-Onset Palmoplantar Keratoderma

- Hyperkeratotic eczema: Tends to be focal, highly pruritic; can be suppressed by treatment and varies in site
- Palmoplantar psoriasis: Tends to produce silvery scale and focal hyperkeratosis not limited to the weight-bearing areas often in association with nail/joint involvement and typical lesions in other skin sites
- Acquired punctate keratoses: Punctate keratoses appearing later in life; can be associated with malignancy, usually in middle age
- Arsenical keratoses: Bead-like palmoplantar keratoses in chronic arsenical ingestion in association with raindrop pigmentation, and susceptibility to non-melanoma skin cancer in those living in areas with ground contamination of drinking water
- Chronic tinea pedis: Can produce extensive hyperkeratosis together with powdery scaling, but clears completely with appropriate antifungal therapy, unlike the secondary infection of palmoplantar keratodermas

ita type 1 (painful callosity syndrome), and is largely due to the pain of walking on pebble-like masses. However, it does not appear greatly improved by removal of hyperkeratotic material, and the fragility of the skin may be exacerbated. Therefore, patients may need additional pain-relieving medication, including analgesics and drugs for neuropathic pain. Specialized footwear to disseminate weight can also help to make the patients more comfortable.

- Difficulty in walking: Secondary to pain on walking, patients may require aids for walking, such as crutches and wheelchairs.
- Use of hands for work and fine movements: Thickening of the palmar epidermis produces a gauntlet-like stiffness in the hands and fingers, which blunts sensation and makes fine movements more difficult, which limits available occupations.
- Secondary infections: Particularly when hyperhidrosis or maceration of the skin are found, there is a tendency to secondary infection, particularly tinea pedis and pitted keratolysis. The inflammatory response may exacerbate the skin thickening, and such patients may be helped by the intermittent use of systemic antifungal drugs, particularly terbinafine, and topical agents countering yeasts, corynebacteria, and dermatophytes.
- Some keratodermas are complicated by progressive disabilities of other organs, which may require specific therapies, including treatment of cardiac dysrhythmias, hearing aids, etc.

TREATMENT

- Physical débridement: Regular chiropody can help to reduce keratotic masses, and patients are often expert at self-treatment in this area
- Topical keratolytic agents: Salicylic acid ointment (5 percent to 20 percent), corn plasters (20 percent to 40 percent salicylic acid), and benzoic acid compound ointment all help to soften the hyperkeratotic materials and aid removal of hyperkeratotic debris with a foot file. The use of 40 percent to 60 percent propylene glycol in aqueous cream under occlusion at night can also soften and assist removal of callosities.
- Treatment of hyperhidrosis: Hyperhidrosis may be a separate requirement, which can be helped by regular potassium permanganate soaks or aluminium chloride hexahydrate lotion. Other physical treatments, such as iontophoresis and Botox injections, are difficult in the presence of gross skin thickening.
- Antifungal creams and systemic antifungal agents may need repeated intermittent courses (e.g., terbinafine initially full treatment and then 1 week per month).
- Retinoids: Acitretin 10 to 20 mg/day (isotretinoin in women of childbearing age) may have a direct benefit in normalizing hyperkeratotic skin, particularly in diseases caused by keratin or connexin mutations. However, treatment is required lifelong and then complications such as periosteal hyperostosis become a significant risk. In addition, the removal of the hyperkeratosis may increase the sensitivity and fragility of the underlying epidermis, and this limits their usefulness.
- Genetic therapies: As the genetic basis of the different diseases become apparent, the mechanisms of manipulating gene expression by small molecules or gene therapy become possible.[7] However, given the diversity of the biologic basis and the rarity of the diseases, this is unlikely to be a global cure. Early studies suggesting the use of small interfering RNA for dominant mutations, for example, pachyonychia congenita type I, will require delivery systems that penetrate palmoplantar epidermis. The knowledge about the genetic basis does, however, permit the development of prenatal diagnosis in severe or life-threatening cases.

CHAPTER 49

Acantholytic Disorders of the Skin: Darier-White Disease, Acrokeratosis Verruciformis, Grover Disease, and Hailey-Hailey Disease

Alain Hovnanian

Acantholytic disorders of the skin are a heterogenous group of diseases characterized by loss of intraepidermal coherence with breakdown of intercellular contacts. Several of these conditions are genetically determined, including Darier-White disease (DD) and Hailey-Hailey disease (HHD). The identification of their defective genes as a calcium pump of the sarco/endoplasmic reticulum in DD and a calcium pump of the Golgi apparatus in HHD represents a major breakthrough in the understanding of their pathogenesis. These discoveries have highlighted the key role of Ca^{2+} signaling in intercellular adhesion and differentiation of the epidermis and have significantly improved diagnostic procedures and genetic counseling for patients with these conditions. Although the precise mechanisms remain to be understood, these results open new avenues for research and treatment of these distressing conditions. These advances have also allowed a better classification of related localized acantholytic conditions, namely, epidermal dyskeratotic acantholytic nevi, which are a localized form of DD caused by somatic mosaicism, and acrokeratosis verruciformis (AKV) of Hopf, which was found to be allelic to DD. Thus, defects in the same gene encoding this calcium pump of the endoplasmic reticulum (ER) underlie three related conditions. Unlike for these genetically determined conditions, the pathogenesis of transient acantholytic dermatosis or Grover disease (GD), which does not show a genetic predisposition, remains unknown.

DARIER-WHITE DISEASE

Etiology and Pathogenesis

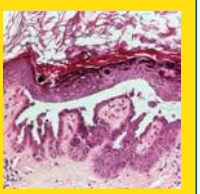
DD is a rare autosomal dominant disease affecting both sexes and all ethnic groups. Its prevalence has been estimated at 1 in 26,300 in Slovenia,[1] 1 in 30,000 in Scotland,[2] 1 in 36,000 in northeast England,[3] and 1 in 100,000 in Denmark.[4,5] Penetrance of the disease is complete, and expression is highly variable between and within affected families. Spontaneous mutations are frequent.

The gene for DD was mapped by linkage analysis to chromosome band 12q23-24 in 1993, with no evidence for genetic heterogeneity in affected families.[6] *ATP2A2* was identified as the defective gene in 1999 using a candidate positional cloning approach.[7] *ATP2A2* encodes sarco/endoplasmic reticulum Ca^{2+} adenosine triphosphatase (ATPase) isoform 2 (SERCA2), a calcium pump transporting Ca^{2+} from the cytosol to the lumen of the ER. The identification of a Ca^{2+} pump as the defective protein in DD came as a surprise and shed light on the key role of Ca^{2+} signaling in the homeostasis of the epidermis.[8]

ATP2A2 spans 76 kilobases (kb), is organized in 21 exons, and encodes a 4.4-kb transcript, which is alternatively spliced into three isoforms: SERCA2a, SERCA2b, and SERCA2c.[9,10] SERCA2a is expressed in the heart and slow-twitch skeletal muscles. SERCA2b and SERCA2c are ubiquitously expressed. SERCA2b is the major isoform detected in the human epidermis.[11] SERCA2 pumps belong to the P-type Ca^{2+} ATPase family, defined by the highly conserved phosphorylation sequence DKTGT. They catalyze the hydrolysis of adenosine triphosphate (ATP) coupled with the translocation of 2 Ca^{2+} ions from the cytosol (100 n*M*) to the ER lumen, where Ca^{2+} is stored at high concentrations (500 μ*M*).[12] SERCA pumps comprise three cytoplasmic domains (the actuator, the phosphorylation, and the ATP-binding domains) linked by five stalk domains to 10 or 11 transmembrane domains anchored in the ER membrane. After binding of two Ca^{2+} ions, SERCA pumps undergo trans-phosphorylation from ATP, which leads to conformational changes and the release of Ca^{2+} ions into the ER lumen. This complex cycle involves critical interactions between cytoplasmic and transmembrane domains, four of which form the two Ca^{2+} ions binding pockets of the molecule. More than 130 ATP2A2 mutations have now been reported in DD patients, the majority of which are different from family to family[7,13–27] (http://www.hgmd.cf.ac.uk/ac/gene.php?gene=ATP2A2). Mutations are distributed across the entire molecule. They disrupt critical functional domains of SERCA2 and show no evidence of clustering or mutation hot spots.

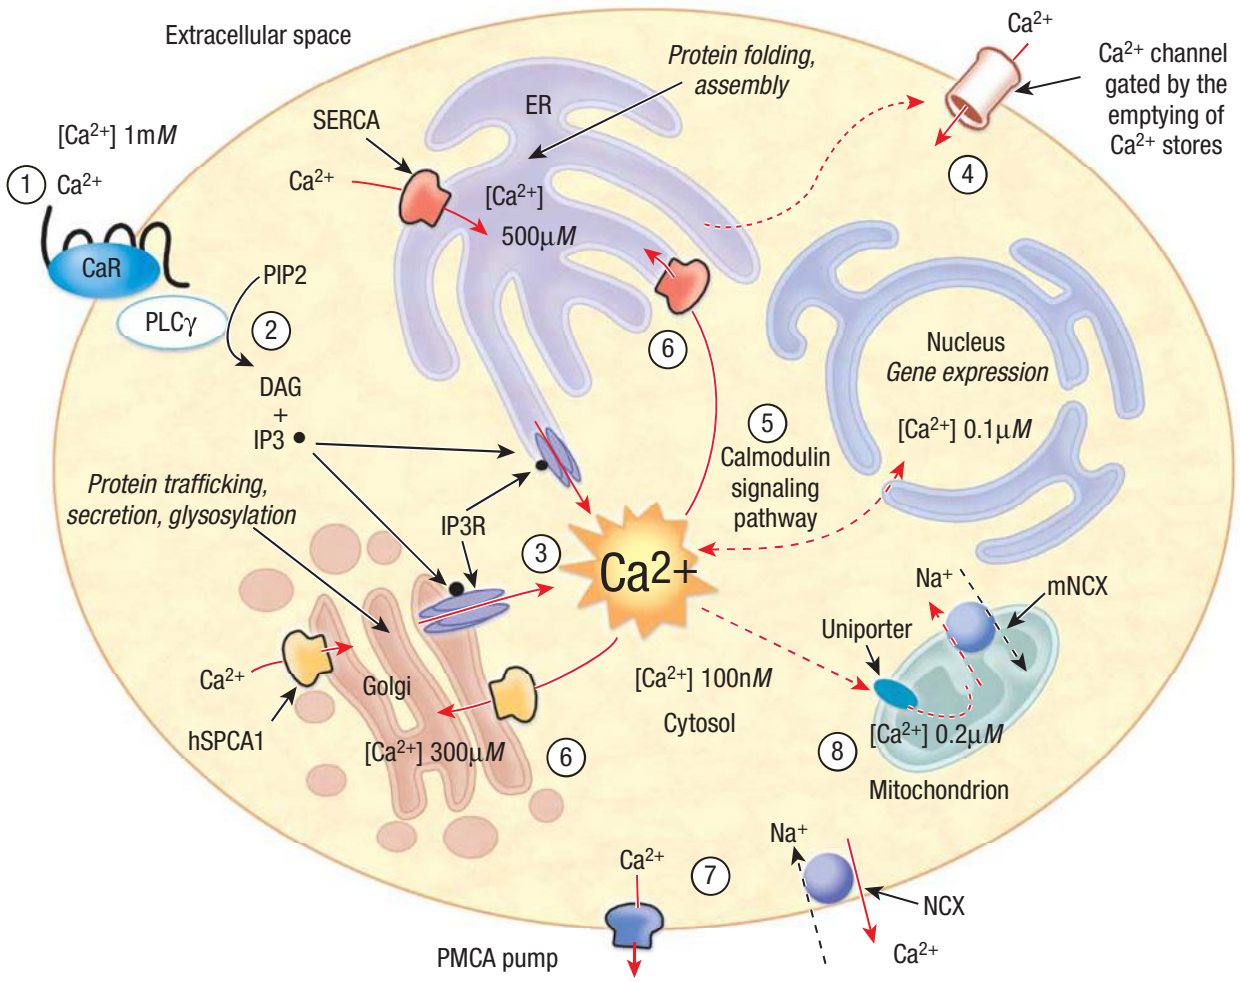
DARIER-WHITE DISEASE (OMIM #124200)

AT A GLANCE



- Also called *Darier disease* or *keratosis follicularis*.
- Late-onset genetic disorder of keratinization.
- First described independently by Darier and White in 1889.
- Clinical features consist of warty papules and plaques in seborrheic areas, specific nail changes, palmo-plantar pits, and papules on the dorsum of the hands and feet.
- Histologic examination of skin lesions shows suprabasal acantholysis in the epidermis with dyskeratotic cells.
- Caused by loss-of-function mutations in the *ATP2A2* gene encoding sarco/endoplasmic reticulum calcium adenosine triphosphatase isoform 2 (SERCA2), which impair intracellular Ca^{2+} signaling.

The majority of the mutations are missense mutations (50 percent) or in-frame deletions or insertions (8 percent), which predict the synthesis of a structurally abnormal protein. Other mutations include nonsense mutations (12 percent) and frameshift mutations (23 percent), which lead to a premature termination codon (PTC) and predict loss of protein expression through nonsense messenger RNA (mRNA) decay. The remaining mutations are splice site mutations (7 percent), the effects of which on the mutated protein remain to be documented. Genotype-phenotype comparison initially suggested that ATP2A2 missense mutations are more frequent in severe or atypical forms, but this has not been confirmed in other studies.[22] However, considerable inter- and intrafamilial variability in the disease phenotype indicates that additional factors influence disease expression.[7,18,23] Three mutations identified in patients with classic DD are of specific interest because they occur in a region of exon 20 that is specific for SERCA2b isoform.[13,28] Each of



▲ **FIGURE 49-1** A simplified representation of Ca^{2+} signaling in keratinocytes. 1. Ca^{2+} binding to its plasma membrane receptor (CaR) activates phospholipase Cγ (PLCγ). 2. This causes the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP2) into inositol 1,4,5-tris-phosphate (IP3) and diacylglycerol (DAG). 3. IP3 binds to its receptor (IP3R) at the surface of the endoplasmic reticulum (ER) and Golgi apparatus, which causes the depletion of intracellular stores and induces an increase in intracellular Ca^{2+} levels. 4. This increase triggers the opening of Ca^{2+} release–activated channels in the plasma membrane, which leads to a sustained increase in Ca^{2+} intracellular levels. 5. Ca^{2+} binds to calmodulin; this activates calcineurin and calmodulin-dependent protein kinases, which regulate gene transcription through phosphorylation/dephosphorylation of transcription factors. 6. Active Ca^{2+} transport by the different sarco/endoplasmic reticulum calcium adenosine triphosphatase (ATPase) pumps (SERCA1 to SERCA3) and human secretory pathway Ca^{2+}/Mn^{2+}-ATPase (hSPCA1) pump is essential to replenish ER and Golgi Ca^{2+} stores, respectively. hSPCA1 is also required for Mn^{2+} influx into the Golgi apparatus (not indicated here). 7. Ca^{2+} efflux to the extracellular space involves plasma membrane Ca^{2+}–ATPases (PMCA) and Na^{+}/Ca^{2+} exchangers (NCX). 8. Mitochondria take up Ca^{2+} released from the internal stores during Ca^{2+} signaling via the Ca^{2+} uniporter and return it to the cytosol through an NCX. Thus, Ca^{2+} homeostasis requires differential Ca^{2+} concentrations in the cytosol, the sarco/endoplasmic reticulum, the Golgi apparatus, the mitochondria, and the nucleus of the cell. The largest store of cellular Ca^{2+} is located in the ER lumen and in Ca^{2+}-binding proteins. Ca^{2+} signaling is highly regulated and generated by influx through Ca^{2+} receptors, release from internal stores (ER, Golgi apparatus, mitochondrion), and sequestration by Ca^{2+} pumps (SERCAs, hSPCA1) and Ca^{2+} exchangers. mNCX = mitochondria Na^{2+}/Ca^{2+} exchanger.

these mutations leads to a PTC, which indicates that loss of SERCA2b expression is sufficient to cause DD and that SERCA2a isoform cannot compensate for it. This finding is consistent with the fact that the most prominent expression of SERCA2b is in the epidermis, although both isoforms are expressed in cultured keratinocytes.[11,23]

The role of extracellular Ca^{2+} in keratinocyte adhesion and differentiation has been well documented, but the key function of SERCA2b in intracellular Ca^{2+} homeostasis in the epidermis was unsuspected. In normal keratinocytes, there is an increasing epidermal gradient in the normal skin, from the basal layer to the superficial layers. High extracellular concentrations are required for epidermal intercellular adhesion, differentiation, and cornification. Ca^{2+} signaling involves binding of raised extracellular Ca^{2+} to a Ca^{2+} plasma membrane receptor, which activates phospholipase C and generates inositol 1,4,5-tris-phosphate (IP3) and diacylglycerol from phosphatidylinositol bisphosphate (Fig. 49-1). IP3 in turn acts as a second messenger, binding to its receptors on the ER (and Golgi apparatus) to trigger release of Ca^{2+} from the intracellular stores into the cytoplasm. Emptying of ER Ca^{2+} stores activates an influx of extracellular Ca^{2+} through plasma membrane Ca^{2+} channels, which function like store-operated channels (capacitive entry mechanism).[32] The molecular identity of these channels that amplify the Ca^{2+} response has not been clearly established, but they could include transient receptor potential channels.[33] The SERCA2 pump plays a key role in Ca^{2+} signaling by refilling the internal Ca^{2+} reservoir of the ER, which is considered the major intracellular Ca^{2+} store. On stimulation, the release of Ca^{2+} from the

ER store will lead to specific cellular responses, depending on the amplitude, frequency, and sub-cellular location of the Ca^{2+} signal. Ca^{2+} triggers the switch between keratinocyte proliferation and differentiation. The increase of intracellular Ca^{2+} levels activates calmodulin, a major Ca^{2+}-binding protein that plays a key role in the control of gene transcription by Ca^{2+}. This results in the activation of the cytosolic calmodulin-dependent phosphatase calcineurin and the family of Ca^{2+}/calmodulin-dependent protein kinases. Both types of enzymes contribute to the regulation of cell division and differentiation. Calcineurin dephosphorylates the cytoplasmic NFAT (nuclear factor of activated T cells) proteins, which allows their translocation into the nucleus and the induction of their downstream target genes. It is of interest to note that cyclosporin A, tacrolimus, and pimecrolimus are calcineurin inhibitors (see Chap. 221). Activation of the Ca^{2+}/calmodulin-dependent protein kinase cascade involves three distinct kinases that regulate transcription through phosphorylation of nuclear factors and histone acetylation, which leads to transcriptional activation or inhibition. By keeping appropriate Ca^{2+} concentrations in the ER lumen, SERCA2 also plays an essential role in protein synthesis, chaperone-dependent processing, and post-translational modification of membrane and secreted proteins, which require a unique calcium-rich environment.[34] Ca^{2+} is required for the assembly of desmosomes and adherens junctions as well as actin polymerization.[35]

A change in the Ca^{2+} ER luminal content is likely to have a major effect on Ca^{2+} signaling, protein post-translational modifications, and trafficking. Although no glycosylation defect of the desmosomal proteins was detected in DD keratinocytes, in culture trafficking of desmoplakin to the membrane is significantly hindered.[42] Defective expression of this key molecule that links the cytoskeleton to the desmosomal complexes could contribute to impaired cell-to-cell adhesion in the epidermis in DD. Finally, Ca^{2+} plays a key role in the transcriptional regulation of a wide range of genes that are essential for epidermal cell-to-cell adhesion and terminal differentiation, which suggests that abnormal Ca^{2+} signaling could have a profound impact on the transcription of these genes.

The observation that exposure to ultraviolet B (UVB) irradiation, heat, and infection triggers disease manifestations indicates the role of external factors in unmasking the basic defect in DD. In the absence of stress, SERCA2 deficiency can be compensated by increased expression of the normal allele and/or other regulatory systems. Triggering factors would disrupt this subtle balance by downregulating ATP2A2 or increasing the requirement for SERCA2 to maintain a unique Ca^{2+} content in the lumen. Because only one copy of ATP2A2 is functional, reduction of SERCA2 levels would be excessive, or compensation would not reach adequate levels. Consistent with this possibility, UVB irradiation and pro-inflammatory cytokines have been shown to downregulate ATP2A2 as well as ATP2C1 mRNA expression.[43] Reduced levels of SERCA2 would result in inappropriate Ca^{2+} concentrations in the lumen, causing dysfunction of calcium-dependent chaperone molecules that leads to impair folding, assembly, and/or trafficking of proteins. Whether this preferentially affects proteins playing a key role in cell-to-cell adhesion and/or differentiation or affects protein processing in general remains to be determined.

▲ **FIGURE 49-2** Hyperkeratotic papules coalescing into plaques in seborrheic areas of the upper chest in a patient with Darier-White disease.

▲ **FIGURE 49-4** Macerated plaques of confluent and keratotic papules in the axillae.

Clinical Findings

Onset of the disease is usually around puberty. The majority of patients develop the first lesions between 10 and 20 years of age. Typical lesions are greasy keratotic papules, skin-colored, yellow-brown or brown, which may be isolated or may form relatively large, crusted, and confluent plaques. The sites of predilection are the seborrheic areas of the trunk (Figs. 49-2, 49-3) and face: the upper chest, the back, the sides of the neck, the forehead, the ears, and the scalp. The groin, axillae (Fig. 49-4), and anogenital region are also frequently involved. The skin lesions can become vegetating in the folds and are often infected, malodorous, and responsible for major discomfort. They can be limited or form extensive plaques during acute phases. Careful examination of the palms and soles will frequently reveal small pits or punctuated keratoses, which are highly suggestive of DD (Fig. 49-5). Hands and feet can also show discrete flat, skin-colored papules on the dorsal areas, similar to AKV of Hopf.[4]

Nail abnormalities are an almost constant feature and are highly specific for

◀ **FIGURE 49-3** Inflammatory plaques in the submammary region, with fissures and maceration. Note that the fingernails are dystrophic.

▲ **FIGURE 49-5** Plane keratotic papules of the palms.

the disease. The nails are fragile and split easily. They show a combination of red and white longitudinal stripes, have a V-shaped nick at the free margin of the nail, and show subungual hyperkeratosis (Fig. 49-6).

The mucous membranes also can be affected. The hard palate, oral mucosa, gingivae, esophagus, vulva, and rectum may be sites of whitish small papules, often densely grouped (leukoplakia).[44] Blockage of the salivary glands has been reported. Intrafamilial differences in disease severity have been described in several studies, which indicates that additional genetic and/or environmental factors influence disease expression.[18]

Histopathology

Histologic examination shows hyperkeratosis, focal dyskeratosis (premature and abnormal keratinization of single keratinocytes) associated with suprabasal acantholysis leading to suprabasal clefts (Fig. 49-7). The rounded eosinophilic dyskeratotic cells are called *corps ronds* in the stratum spinosum, and *grains* in the upper layers of the epidermis. They are thought to correspond to apoptotic keratinocytes. Electron microscopy has revealed separation of the keratin filaments from the desmosomes with clumping of perinuclear tonofilaments.[45]

▲ **FIGURE 49-6** Dystrophic fingernails showing fragility, splitting, and red and white longitudinal stripes.

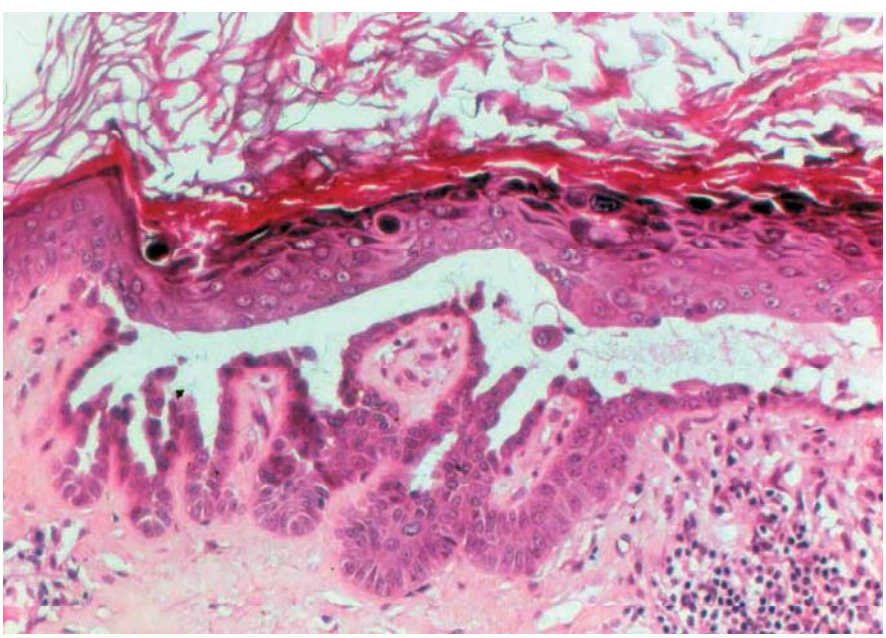
Associated Manifestations

Behavior and learning difficulties have been observed in patients with DD, but they may be, at least in part, secondary to the social handicap caused by the disease. Neuro-psychiatric abnormalities have also been reported in families with DD.[46] These include seizures, mild mental retardation, bipolar disease, and schizophrenia. Familial co-segregation of DD and bipolar disorder has been reported in several families and strongly supports the existence of a bipolar disorder susceptibility gene in the DD region.[47] However, ATP2A2 has been excluded as a common susceptibility gene for bipolar disease.[48] These observations, together with the finding of SERCA2b expression in the brain[49] and the importance of calcium signaling in neurons, raise the question of whether skin and neuro-psychiatric conditions are occurring independently or represent expression of the same genetic defect affecting both skin and brain.[17]

Clinical Forms

Some patients develop erosive or bullous forms; others have malodorous, vegetating lesions in the flexures. Pruritic and papulovesicular lesions can be seen in some DD patients, similar to those in GD (see Grover Disease). Rare clinical variants include cornifying forms on the legs,[50] comedone-like lesions,[51] and hemorrhagic macules on palms and soles.[52] In pigmented skin, DD may present as hypopigmented macules and papules.[53]

Two particular forms of the disease should be distinguished. In the first,



▲ **FIGURE 49-7** Histologic preparation of affected skin in Darier-White disease showing suprabasal cleft of the epidermis containing acantholytic cells, associated with rounded dyskeratotic cells with a dark nucleus ("corps ronds" or "grains") and hyperkeratosis.

▲ **FIGURE 49-8** Acantholytic epidermal nevi (segmental Darier-White disease). Limited and unilateral distribution of keratotic and inflammatory papules following Blaschko's lines on the breast and axillary region.

acantholytic dyskeratotic epidermal nevi, the localized and unilateral keratotic papules of DD follow Blaschko's lines[54,55] (Fig. 49-8). Molecular analysis in these patients has shown that they represent mosaic forms of DD, carrying a postzygotic ATP2A2 mutation in affected areas only.[26,56] There has been no report of patients with segmental DD having a child with generalized DD, and the risk of transmission of a generalized form remains unknown.

Acral forms are difficult to distinguish from AKV of Hopf, which could be considered a clinical variant of DD, because both diseases are due to ATP2A2 mutations (see Acrokeratosis Verruciformis).[14,57]

Differential Diagnosis

The classic form of DD is highly suggestive of the condition. However, DD can be misdiagnosed as seborrheic dermatitis or acne in the initial stages. The diagnosis of clinical variants can sometimes be challenging (Box 49-1). Acral forms resemble plane warts. Erosive or bullous forms predominating in the folds may be difficult to distinguish from HHD[58] (see Hailey-Hailey Disease) and pemphigus vulgaris (see Chap. 52). However, HHD usually presents later in the third decade and shows painful flexural erosions with rhagades and no keratotic papules. Vegetating forms need to be distinguished from pemphigus vegetans (see Chap. 52). Pruritic and papulovesicular forms resemble GD. However, GD occurs in patients with long-term sun damage and is usually transient, although chronic forms have been described.[59]

Course

The skin lesions generally appear between early childhood and the age of 20 years. The condition runs a chronic relapsing course, with exacerbations throughout life. Some patients will have relatively mild disease, whereas others, sometimes within the same family, will develop a more severe form. In particular, the skin lesions are exacerbated by exposure to sunlight or artificial UVB radiation, heat, sweating, friction, and infections. Patients with DD appear to have an increased susceptibility to herpes simplex and chronic pyogenic infections. Rare cases of recurrent corneal ulcerations with perforation have been reported.[60]

Treatment

Patients with mild disease will benefit from advice about sun protection (sun avoidance and use of sunscreens in the summer) and avoidance of heat. When skin lesions are limited, emollients containing urea or lactic acid can reduce crusting. Topical applications of tretinoin or isotretinoin improve the hyperkeratosis of localized lesions, although irritation limits their value. Topical steroids may help in reducing irritation but are not effective alone. New retinoids such as tazarotene are somewhat effective and are tolerated better than first-generation retinoids. Antiseptics (topical or in the bath), antibiotics, and antifungal medications are helpful to prevent or treat pyogenic and fungal infection. Herpes infection should be suspected when lesions are painful and exacerbated and requires antiviral treatment with acyclovir.

Box 49-1

Differential Diagnosis of Darier Disease

- Classic form
  - Seborrheic dermatitis
  - Seborrheic keratoses
  - *Candida* infection (submammary)
- Papular vesicular form
  - Grover disease
- Erosive, bullous form
  - Hailey-Hailey disease
  - Pemphigus vulgaris
  - Langerhans cell histiocytosis
  - *Candida* infection
  - Impetigo
- Vegetating form
  - Pemphigus vegetans
- Acral form
  - Verrucae planae

For those with more severe disease, oral retinoids such as acitretin are the most effective treatment. Their efficacy lasts only as long as the treatment is continued. The initial dose is usually 25 to 30 mg per day for 2 to 4 weeks, and if the drug is well tolerated, the dose can be increased up to 60 mg for 2 months. The patient must be monitored carefully for possible side effects (see Chap. 229). After initial clearing of the lesions, the dosage should be reduced progressively and stopped (in winter) or maintained at as low a level as possible to avoid relapse.[4] Topical tacrolimus has been used successfully to treat extensive DD.[61]

The disease can cause a considerable social handicap and can require specific psychological support by a medical psychologist. Genetic counseling should be offered, although prenatal diagnosis of the disease should be restricted to extremely disabling forms.

ACROKERATOSIS VERRUCIFORMIS

Genetics

AKV is inherited in an autosomal dominant fashion, but sporadic cases have been reported. A heterozygous Pro602Leu missense mutation in the ATP2A2 gene in a large British family affected with AKV has been identified.[14] This mutation is located in the ATP-binding domain of SERCA2 and has not been reported in patients with classic DD. Functional analysis showed that it abolishes Ca^{2+} transport. These results established that AKV and DD can be due to mutations in the same gene (i.e., are allelic disorders). However, one study in a large Chinese family did not find evidence for the involvement of ATP2A2, which raises the possibility of genetic heterogeneity in AKV.[62]

Clinical Manifestations

The onset of AKV is early in life, often at birth or later in infancy. The disease is characterized by multiple small, flat, flesh-colored, warty papules typically located on the dorsum of the hands and feet[63] (Fig. 49-9). Grouped or isolated papules can also develop on the knees, elbows, extensor aspects of lower legs, forearms, and wrists. Punctate keratoses and pits on the palms and soles can be present and can interrupt the dermal ridges in the finger pads and palms. Palmar skin may be thickened. Varying de-

ACROKERATOSIS VERRUCIFORMIS (OMIM #101900)

AT A GLANCE

- Rare, heritable disorder of keratinization, originally described by Hopf in 1931.
- Usually presents with multiple small flat-topped papules predominantly on the dorsum of the hands and feet.
- Histopathologic analysis shows hyperkeratosis, hypergranulosis, and acanthosis with "church spikes," circumscribed elevations of the epidermis, without acantholysis or dyskeratosis.
- Allelic with Darier-White disease: Both are due to defects in ATP2A2.

grees of nail involvement have been reported, including longitudinal striations, splitting, and subungual hyperkeratosis with V-shaped nicks at their free margins. The rest of the skin is clear, with no involvement of seborrheic areas.

Histopathology

The classic histopathologic findings of AKV include hyperkeratosis, hypergranulosis, and acanthosis with papillomatosis. Localized elevations of the epidermis resembling "church spikes" are frequent and typical of AKV (but not constant) (Fig. 49-10). There are no features of dyskeratosis or acantholysis, which are classic features of DD lesions.

Clinical Forms

A rare linear variant with persistent localized unilateral lesions has been reported in two unrelated Saudi patients.[64]

Differential Diagnosis

AKV should be distinguished from plane warts and epidermodysplasia verruciformis (see Chap. 196) by histopathologic features.

Course

Lesions tend to persist throughout life, increase slowly in number, and become more prominent after sun exposure. Transformation to squamous cell carcinoma has been reported in two cases.[62,65,66]

Treatment

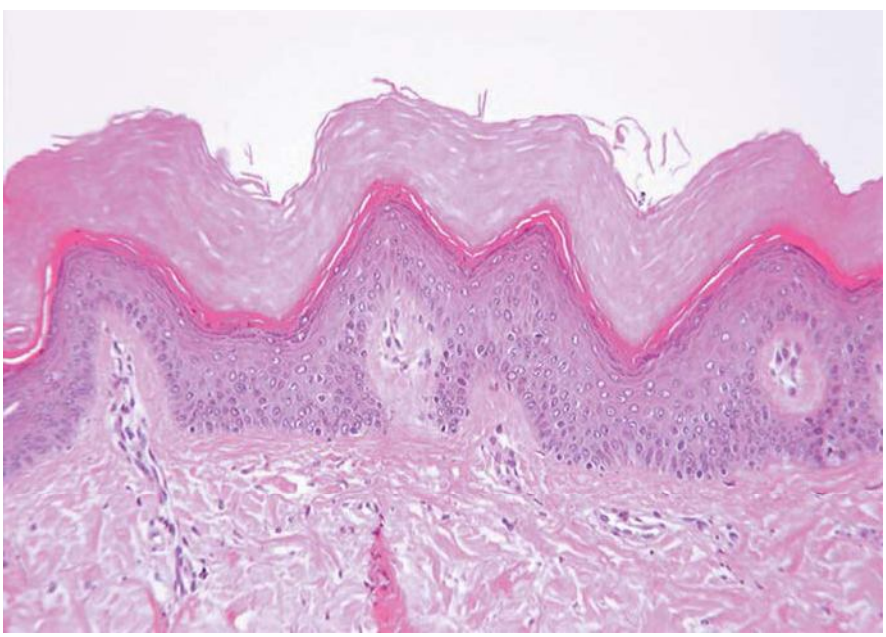
Superficial ablation is the most effective treatment. Applications of retinoic acid, cryotherapy, and carbon dioxide laser ablation have been effective.

▲ **FIGURE 49-9** Small, flesh-colored papules over the dorsum of the hand in a patient with acrokeratosis verruciformis of Hopf.

GROVER DISEASE

Etiology and Pathogenesis

GD is not a rare disease and shows no evidence for genetic predisposition.[67]



▲ **FIGURE 49-10** Histopathologic features of Hopf disease showing acanthosis and hyperkeratosis with "church spike" elevations of the epidermis, but no acantholysis or dyskeratosis. (Used with permission from Dr. Laurence Lamant, Department of Pathology, Purpan Hospital, Toulouse, France.)

GROVER DISEASE (TRANSIENT ACANTHOLYTIC DERMATOSIS)

AT A GLANCE

- First described in 1970.
- Pruritic, polymorphic, cutaneous papulovesicular eruption on the trunk.
- Occurs in adults after long-term sun damage.
- Histologic examination shows variable focal acantholytic dyskeratosis.
- Classic (transient) form resolves within a few months, but a persistent form has been recognized.
- There is no evidence for genetic predisposition.

The cause of the disease is unknown. The majority of patients are white males older than 40 years, with solar damage. Electron microscopy shows clumping of keratin filaments and loss

of desmosomes. Immunohistologic staining reveals internalization and redistribution of desmosomal attachment plaques.[68] Because GD shares several clinical, histologic, and ultrastructural features with DD, mutations in ATP2A2, the defective gene in DD, have been sought in patients with persistent GD.[59] No ATP2A2 mutation was identified in the skin (lesional and normal) or in leukocytes in four patients, which indicates that GD is not allelic to DD. Thus, although DD and GD share striking clinical and histopathologic features, the mechanism underlying acantholytic dyskeratosis in GD remains unknown.

Clinical Findings

The disease onset is around 40 years of age. The typical patient is a male with fair skin and a history of habitual sun exposure. GD presents with an acute eruption with pronounced itching often disproportionate to the eruption. Red papules, papulovesicles, and eczematous plaques with erosions and crusts are scattered, or rarely grouped (Figs. 49-11, 49-12). The lesions are disseminated on the trunk and can extend to the neck and proximal limbs.[69–71] Excessive sun exposure, heat, sweating, and exposure to ionizing radiation are precipitating factors.[72] There are usually no associated findings.

Histopathology

Four histologic types have been described in GD, with different patterns of acantholysis.[69,71,73] They comprise a DD type with suprabasal cleft and dyskeratotic cells; a pemphigus-like type with acantholytic cells within suprabasal cleft; an HHD-like type with acantholysis of most of the stratum malpighii; and a spongiotic form with acantholytic cells within vesicles (Fig. 49-13). These patterns are frequently in combination and may correspond to various stages of the disease. The histologic changes are often localized, so that multiple biopsies and sections are required. The dermis often shows an inflammatory cell infiltrate. Indirect immunofluorescence testing gives negative results.

Clinical Forms

A bullous form has been described.[74] More recently, a widespread form of GD with lentiginous sun-induced "freckling" was reported in two females.[75] Many cases clear within a few months (transient acantholytic dermatosis), whereas others persist for years (persistent acantholytic dermatosis), especially in elderly patients. Persistent disease runs a chronic relapsing course and is often associated with asteotic eczema, atopic dermatitis, and contact dermatitis. Some patients complain of weakness, and cancers have been associated.

▲ **FIGURE 49-11** Grover disease. Pruriginous papules on the trunk resembling folliculitis in a 60-year-old man.

Differential Diagnosis

Prurigo simplex, folliculitis, papular eczema, scabies, papular urticaria, miliaria rubra, and dermatitis herpetiformis should be excluded (Box 49-2). GD should also be distinguished from other acantholytic diseases, including pemphigus vulgaris, DD, and HHD. A unilateral transient acantholytic dermatosis (GD) along Blaschko's lines has been reported, although the differential diagnosis with linear DD remains difficult.[76,77]

▲ **FIGURE 49-12** Grover disease. Discrete papulovesicular lesions of the supermammary region with crusts in a 53-year-old man.

Box 49-2

Differential Diagnosis of Grover Disease

Consider

- Prurigo simplex
- Folliculitis
- Papular eczema
- Scabies
- Miliaria rubra

Rule Out

- Dermatitis herpetiformis
- Darier-White disease
- Hailey-Hailey disease
- Pemphigus vulgaris

Course

In the transient form, the course is transitory, and spontaneous healing often occurs within a few weeks or 2 months. In older patients, the disease may last longer (persistent GD) and can continue for years. The prognosis is variable, but the disease is usually chronic, and the severity of the condition fluctuates.

Treatment

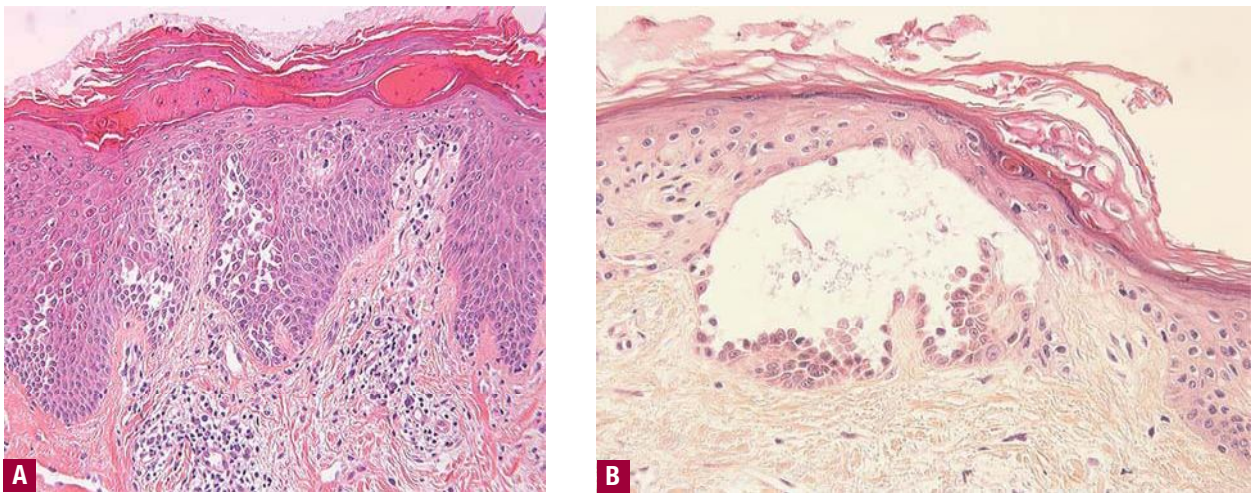
The effectiveness of treatments is difficult to assess because of the variable course. Precipitating factors, including UV radiation, heat, sweating, and topical irritants, should be avoided. In mild cases, topical corticosteroids, emollients, calcipotriol, urea, lactic acid, and zinc oxide are useful in relieving irritation and controlling the pruritus. In more severe or persistent cases, isotretinoin (40 mg/day), acitretin, oral corticosteroids, and psoralen plus UVA therapy can be effective.[78–83]

HAILEY-HAILEY DISEASE

Genetics

HHD is a rare blistering disease inherited in an autosomal dominant manner. Its incidence has been suggested to be 1 in 50,000. Penetrance in adults is complete, but expressivity is variable. Some forms present with mild lesions resembling eczema, whereas other forms are characterized by severe widespread disease.[84]

The identification of ATP2A2 as the defective gene in DD has guided the search for the gene for HHD. HHD had been linked to chromosome region 3q21-24, with no evidence for locus heterogeneity. Because HHD and DD are very similar both clinically and histologically, the discovery of the crucial role of SERCA2 in cell-to-cell adhesion and differentiation of the epidermis raised the



▲ **FIGURE 49-13** **A.** Hailey-Hailey–like pattern in Grover disease with areas of detached keratinocytes (acantholysis), focal spongiosis, and epidermal hyperplasia. **B.** Pemphigus-like pattern in Grover disease with suprabasal acantholytic cleavage.

possibility that defects in another calcium pump could underlie HHD. This led to the identification of a new gene in the HHD region, ATP2C1, which encodes the related human secretory pathway Ca^{2+}/Mn^{2+} ATPase (hSPCA1), as the defective gene in HHD.[58,85]

The gene spans approximately 30 kb on 3q21 and comprises 28 exons encoding a 4.5-kb transcript. The predicted protein is approximately 115 kd in size. Alternative splicing of ATP2C1 primary transcripts in keratinocytes leads to four splice variants, ATP2C1a to ATP2C1d, which differ by different splicing of exon 27 and/or 28. ATP2C1d is the largest variant, containing exons 27 and 28 in their entirety. ATP2C1 mRNA is ubiquitously expressed. It is highly expressed in human epidermal keratinocytes and at variable levels in other human tissues. Behne and colleagues have shown that human keratinocyte SPCA1 localizes to the Golgi apparatus.[86]

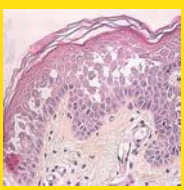
SPCA1 belongs to the SPCA (secretory pathway calcium ATPase) class, which like PMCA (plasma membrane calcium ATPase) possesses only one of the two high-affinity Ca^{2+}-binding sites present in SERCA. On the basis of amino acid sequence alignment, the structure of the SPCA family is thought to be similar to that of the SERCA family, but the single Ca^{2+}-binding site transports a single Ca^{2+} or Mn^{2+} ion. SPCA1 has been shown to transport both ions in the Golgi lumen and therefore plays a major role in cytosolic and intra-Golgi Ca^{2+} and Mn^{2+} homeostasis.[87] SPCA1 has the same apparent transmembrane organization and contains all of the conserved domains found in P-type ion transport ATPases. It exhibits 97 percent amino acid identity to the rat SPLA Ca^{2+} pump of the Golgi apparatus, 49 percent identity to the yeast secretory pathway PMR1 pump, 37 percent identity to human SERCA2, and 31 percent identity to human plasma membrane Ca^{2+} ATPase PMCA2.[85,88]

HHD is caused by mutations inactivating one ATP2C1 allele.[89] More than 80 pathogenic ATP2C1 mutations have been reported to date. The studies have revealed that mutations did not cluster but were scattered across the ATP2C1 gene and show substantial allelic heterogeneity.[28,58,85,90–98] Several recurrent mutations have been identified, some of which result from a founder effect in patients of British extraction.[90] Of these mutations, 20 percent are nonsense mutations and 30 percent are frameshift mutations, which indicates that at least 50 percent of ATP2C1 mutations reported so far lead to PTCs. These mutations predict loss of expression or marked reduction of mutated ATP2C1 via nonsense-mediated mRNA decay, which further supports the possibility that haploinsufficiency of ATP2C1 is a prevalent mechanism for the dominant inheritance of HHD. Nineteen percent of the mutations affect splice sites, but their effects on splicing remains to be determined. Twenty-eight percent of the mutations are missense mutations, whereas the remaining 3 percent are in-frame mutations. These mutations lead to amino acid changes in highly conserved critical functional domains of the Golgi Ca^{2+} pumps in different species (rat, yeast), and between SERCA and PMCA pumps. Some of these mutations occur at amino acid residues, which by site-directed mutagenesis have been shown to abrogate SERCA1 function.[99]

Comparison between genotype and phenotype, however, fails to detect any clear correlation between the nature of the mutation and the clinical features of HHD (age of onset, severity, progression). Extensive inter-familial and intra-familial variation in clinical features has also been

HAILEY-HAILEY DISEASE (OMIM #169600)

AT A GLANCE



- Also called *familial benign chronic pemphigus.*
- Late-onset blistering dermatosis.
- First described by the Hailey brothers in 1939.
- Presents after the third of fourth decade with painful erosions and fissures (rhagades) in the flexures.
- Histologic examination of skin lesions shows extensive loss of intercellular contacts (acantholysis) of suprabasal and upper layers of the epidermal keratinocytes, which gives the appearance of a "dilapidated brick wall."
- Caused by loss-of-function mutations in the ATP2C1 gene encoding the human secretory pathway calcium/manganese adenosine triphosphatase (hSPCA1) of the Golgi apparatus, which impair intracellular Ca^{2+} signaling.

noted, as well as variation between families sharing the same mutation.[90]

Etiology and Pathogenesis

The majority of mutations result in protein instability, whereas others cause lack of Ca^{2+} and/or Mn^{2+} ion transport through different alterations of the catalytic cycle of the SPCA1 pump.[91,92,100] Studies highlight the crucial role of specific residues in the binding of Ca^{2+} and Mn^{2+} to hSPCA1. They also further support the theory of haploinsufficiency as a prevalent mechanism for the dominant inheritance of HHD, which suggests that the level of functional hSPCA1 in epidermal cells is critical.

In view of the ubiquitous expression of ATP2C1, it is not clear why defects in ATP2C1 result in a disease restricted to the skin, and why the disorder is limited to certain areas of the skin. The mechanism by which mutant ATP2C1 cause acantholysis is also unknown. HHD keratinocytes in culture display elevated resting cytosolic Ca^{2+} levels, abnormally low Golgi Ca^{2+} levels, and impaired regulation of excess cytosolic Ca^{2+} in vitro.[58,86] Abnormal Ca^{2+} signaling in HHD keratinocytes correlates with decreased protein levels of ATP2C1. In vivo, clinically normal HHD contains lower Ca^{2+} stores and displays an abnormal Ca^{2+} gradient.[86] Elevated cytosolic Ca^{2+} levels could influence gene expression or alter post-translational modification of target proteins (activation of protein kinase C). Alternatively, low Ca^{2+} or Mn^{2+} concentrations in the Golgi lumen could impair post-translational modifications (proteolytic processing, glycosylation, trafficking, or sorting) of membrane (associated) proteins important in epidermal cell-to-cell adhesion, such as desmosomal components. This may impair desmosome formation and/or stability, leading to the acantholysis characteristic of HHD. It has been suggested that desmosomal glycoproteins differ in their extent of glycosylation among different cell types. Thus, the reason why clinical signs are restricted to the epidermis could be related to a particular glycosylation state that leaves epidermal cells more prone to Ca^{2+} changes. It is also possible that non-cutaneous tissues have compensatory mechanisms to overcome ATP2C1 dysfunction that are missing in the skin. The demonstration of loss of expression and/or function of mutant SPCA1 proteins identified in HHD suggests that epidermal cells are sensitive to levels of hSPCA1 (gene dosage), which may not be the case for other tissues. This could explain why lesions are exacerbated by external factors (sun exposure, sweating, friction) that would place epidermal cells under stress and disrupt a subtle balance maintained in the steady state. In support of this possibility, UVB irradiation and pro-inflammatory cytokines have been shown to downregulate ATP2C1 as well as ATP2A2 mRNA expression.[105] Finally, defective actin reorganization and a marked decrease in cellular ATP have been reported in HHD keratinocytes in vitro, which suggests an additional mechanism in the pathogenesis of HHD.[106]

▲ **FIGURE 49-14** Hailey-Hailey disease (familial benign pemphigus). Hypertrophic and macerated plaque of the axilla with painful fissures (rhagades).

Clinical Manifestations

The disease often manifests in adulthood (30s and 40s) and is characterized by vesicular lesions, painful erosions, and scaly erythematous plaques that occur at sites of friction and flexures (neck, axillae, submammary region, groin, and perineum) (Figs. 49-14, 49-15). Painful fissures (rhagades) in flexures are common and very suggestive of the disease. The lesions are often itchy but painful when scratched. Mucosal involvement is rare, but oral, esophageal, and vulvar lesions are possible. Longitudinal white lines on the fingernails can be seen and are helpful in diagnosing the disease (Fig. 49-16). Penetrance in adults is complete, but expressivity is variable between and within affected families (see Clinical Forms). Flexural forms may become hypertrophic and malodorous.

▲ **FIGURE 49-15** Focal erosive plaque with fissures in the axilla of a patient with Hailey-Hailey disease.

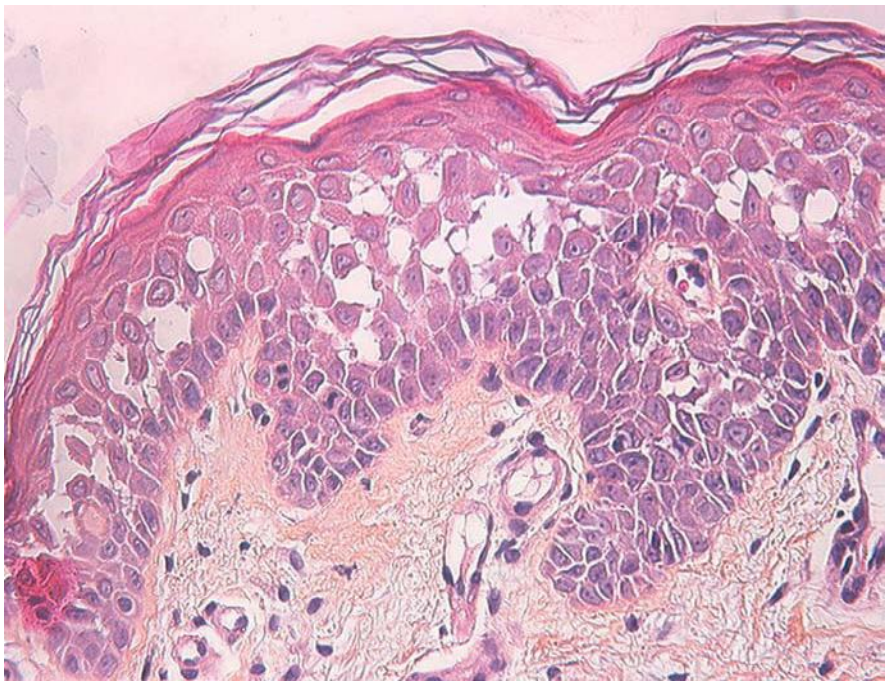
▲ **FIGURE 49-16** White longitudinal stripes on the fingernails of a patient with Hailey-Hailey disease.

Histopathology

Histopathologic examination of skin lesions shows widespread loss of cohesion between suprabasal keratinocytes (acantholysis), giving the appearance of a "dilapidated brick wall" (Fig. 49-17). Vesicle formation or epidermal clefting is possible. Dyskeratosis, when present, is mild. Ultrastructural studies of acantholytic cells have shown perinuclear aggregates of keratin filaments that have retracted from desmosomal plaques.[68]

Clinical Forms

Expressivity of the disease can vary greatly. Mild forms may be limited to nail changes or mild lesions resembling eczema, whereas severe forms display widespread flexural disease, with hypertrophic and malodorous plaques and painful fissures. This can cause considerable pain and distress and can limit patient mobility. There are no extracutaneous manifestations.[84] Two types of mosaicism are seen in patients with HHD. Type 1 segmental manifestation of mosaicism presumably reflects a localized postzygotic mutation.[107] This manifests as a streak or multiple localized streaks of disease along Blaschko's lines in a patient without evidence of the disorder elsewhere. Type 2 mosaicism is



▲ **FIGURE 49-17** Hailey-Hailey disease. Extensive loss of intercellular contacts within the suprabasal and upper layers of the epidermis giving the appearance of a "dilapidated brick wall."

characterized by severely affected unilateral segmental areas along Blaschko's lines superimposed on classic disease,[108] which suggests postzygotic loss of heterozygosity at the ATP2C1 locus.

Differential Diagnosis

HHD shows considerable clinical and histologic overlap with DD, although acantholysis is more widespread in HHD, whereas dyskeratosis is a predominant feature of DD. Because lesions can vary considerably, the disease can be misdiagnosed as eczema; bacterial, fungal, or viral infection; or pemphigus (Box 49-3).

Course

Lesions are frequently induced or exacerbated by UV exposure, sweating, friction, and skin infection. The disease has a chronic fluctuating course, and patients undergo recurrent exacerbations and remissions that can last months to years. The disease can severely affect the quality of life.[109] The development of squamous cell carcinomas on HHD skin lesions has been reported in rare cases.[110]

Box 49-3

Differential Diagnosis of Hailey-Hailey Disease

Consider

- Darier-White disease
- Eczema
- *Candida* infection
- Intertrigo

Rule Out

- Pemphigus vulgaris

Treatment

HHD is a difficult disease to treat, and various therapeutic modalities must be considered. The use of topical corticosteroids in association with antibacterial agents can result in transient improvement. More widespread flares may require systemic antibiotics (erythromycin and tetracyclines). Bacterial culture and sensitivity testing are useful to determine appropriate antibiotics. In patients with refractory disease, the response to dapsone, systemic corticosteroids, retinoids (acitretin or isotretinoin), and immunomodulators (methotrexate, thalidomide, cyclosporine) is usually poor. Treatment with systemic or topical calcipotriol was reported to be efficient.[61,111–113] The exact mechanism of action of vitamin D_3 in treating HHD is unknown, but it could involve an increase in Ca^{2+} intracellular concentration as shown in cultured keratinocytes.[114] More recently, topical application of tacrolimus was also found to be effective.[115] Because this molecule is a calcineurin inhibitor, this raises the question of the role of its signaling pathway in the disease. Finally, topical application of gentamicin was used in an HHD patient harboring a nonsense mutation in ATP2C1 because of the potential of aminoglycosides to induce read-through of nonsense mutations in human cells. This led to a significant improvement in the patient's lesions, which indicates the potential value of this approach for patients with a nonsense ATP2C1 mutation.[116] Surgery remains an option in the absence of response to these treatments.

Diet and activity advice is also useful. To help minimize friction, patient weight should be maintained at appropriate levels, and comfortable clothing should be worn to prevent heat, moisture, and friction.

CHAPTER 50

Porokeratosis

Grainne M. O'Regan
Alan D. Irvine

Porokeratosis is a morphologically distinct disorder of keratinization, characterized clinically by hyperkeratotic papules or plaques surrounded by a thread-like elevated border that expands centrifugally. Histologically, a thin column of parakeratotic cells extends throughout the stratum corneum and is seen in all variants. This distinctive histopathologic feature, known as the *cornoid lamella*, corresponds to the raised hyperkeratotic border evident clinically.

Several clinical variants of porokeratosis have been described, some with overlapping features (Box 50-1). Although various forms are recognized, the clinical distinction between the different variants may not be justified, because overlap occurs among the varieties. Reports of one type of porokeratosis co-existing with other forms and different types developing in multiple members of an affected family suggest more similarities than disparities, particularly in the disseminated forms.[1,2]

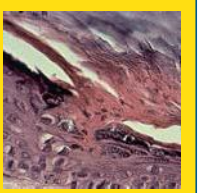
HISTORICAL ASPECTS

ETIOLOGY AND PATHOGENESIS

Porokeratosis is a genetically heterogeneous disorder with several loci identified to date; however, the pathogenetic mechanisms remain elusive. Loci at chromosome bands 12q23.2-24.1 and 15q25.1-26 (DSAP1 and DSAP2) have been reported in familial disseminated superficial actinic porokeratoses; a further locus has been identified for disseminated superficial porokeratosis (DSP) at 18p11.3.[10–12] The locus at DSAP1 corresponds to a candidate gene, *SART3*, that encodes a tumor rejection antigen and is thought to be involved in the regulation of messenger RNA splicing. Mutations in *SART3* may thus result in altered proliferation and transformation of epithelial cells. Fine mapping of the locus at DSAP1 has also revealed mutations in another potential candidate gene, *SSH1*, which encodes a phosphatase that plays a key role in actin dynamics.[13,14] Porokeratosis punctata palmaris et plantaris maps to a 6.9-centimorgan region at chromosome band 12q24.1-24.2 that overlaps with the region identified for DSAP1, which suggests that the two forms are allelic.[15]

The centrifugal expansion of individual lesions is postulated to reflect the migration of a mutant clone of keratinocytes.[16] Supporting this mutant clone theory are findings of abnormal DNA ploidy and chromosomal abnormalities in lesional keratinocytes.[17] The tumor suppressor proteins p53 and pRb are overexpressed in keratinocytes immediately beneath and adjacent to the cornoid lamella, although to date p53 mutations have not been identified.[18–22] Cytogenetic abnormalities in fibroblasts, particularly on chromosome 3, have also been documented.[23,24] Decreased mdm2, abnormal expression of psi-3, cytokeratins, filaggrin, and involucrin have also been reported.[25,26] The increased prevalence of porokeratosis in immunosuppressed patients suggests that impaired immunity may be permissive in genetically predisposed individuals.[27–30] Other reported triggering factors such as exposure to ultraviolet light, together with the increased potential for malignant transformation, highlight the

POROKERATOSIS AT A GLANCE



- A chronic progressive disorder of keratinization, characterized clinically by hyperkeratotic papules or plaques surrounded by a thread-like elevated border that expands centrifugally.
- At least six clinical variants of porokeratosis have been described.
- The classic form, porokeratosis of Mibelli, presents in infancy or childhood as asymptomatic small brown to skin-colored annular papules with a characteristic raised border.
- Disseminated superficial actinic porokeratosis is the most common type, with multiple papules distributed symmetrically on sun-exposed areas.
- Linear porokeratosis presents at birth or in childhood with lesions distributed along Blaschko's lines.
- Punctate porokeratosis appears during or after adolescence as 1- to 2-mm papules on the palms or soles.
- Histologically, a thin column of parakeratotic cells termed the *cornoid lamella*, corresponding to the hyperkeratotic border, extends throughout the stratum corneum and is seen in all variants.
- A genetically heterogeneous disorder; the majority of forms may be inherited as an autosomal dominant trait.
- Malignant epithelial neoplasms are reported in all sub-types except the punctate variety.

▲ **FIGURE 50-1** Porokeratosis of Mibelli is characterized by a single large lesion with a clearly defined edge. The scaling is not clearly seen at the border because of the interdigital location of this lesion.

dysplastic potential of affected keratinocytes. Malignant degeneration has been described in all variants of porokeratosis, with the exception of the punctate variety.[31–33]

CLINICAL FINDINGS

Porokeratosis of Mibelli

Classic porokeratosis of Mibelli begins during infancy or childhood as asymptomatic small brown to skin-colored annular papules with a characteristic annular border (Fig. 50-1). The well-demarcated hyperkeratotic border is usually more than 1 mm in height, with a characteristic longitudinal furrow. The center of the lesion may be hyperpigmented, hypopigmented, depressed, atrophic, or anhidrotic. Lesions range in diameter from millimeters to several centimeters, but giant lesions measuring up to 20 cm may occur. Such giant porokeratoses are rare and occur predominantly on the lower leg and foot. Large lesions are associated with a higher malignant potential.[33] Multiple lesions may arise; however, they are usually regionally localized and unilateral. The condition may be familial and inherited as an autosomal dominant trait. Lesions persist indefinitely.

Disseminated Superficial Actinic Porokeratosis

Disseminated superficial actinic porokeratosis (DSAP) is the most common of the porokeratoses. Lesions are characteristically uniformly small, annular, asymptomatic or mildly pruritic papules ranging from 2 to 5 mm in diameter, distributed symmetrically on the extremities. Lesions are more generalized than other forms of porokeratosis, with typically in excess of 50 lesions located predominantly in sun-exposed sites (Fig. 50-2A and B). A history of increased prominence with sun exposure is usually reported. Although widespread, lesions typically spare palms, soles, and mucous membranes. Compared with porokeratosis of Mibelli, the hyperkeratotic border is characteristically more subtle. As the lesions progress, the older, central area becomes atrophic and anhidrotic. DSAP tends to be inherited as an autosomal dominant disorder, with the earliest reported age of onset at 7 years, and is usually fully penetrant by the third or fourth decade of life.[11] Initial reports of induction of lesions by exposure to ultraviolet light and hypersensitivity of DSAP-derived fibroblasts to x-rays have not been consistently reproduced, and the pathogenesis of DSAP remains unknown.[18,34–36]

Disseminated Superficial Porokeratosis

DSP also shows an autosomal dominant pattern of inheritance and has its onset in the third or fourth decade of life. Lesions primarily are morphologically identical to those of DSAP, occur on the extremities, and are typically distributed symmetrically, but do not spare sun-protected areas as in DSAP. As with DSAP, in excess of 100 lesions may be disseminated, with a predilection for the extensor surfaces of the extremities. Notably, involvement of the face is rare in both DSAP and DSP. In both disseminated forms, there is a reported female predominance, with a female-male ratio of 3:1.

Disseminated Superficial Porokeratoses of Immunosuppression

Disseminated superficial porokeratoses of immunosuppression are recognized after renal, hepatic, and cardiac transplantation, electron beam irradiation,[37] immunosuppressive chemotherapy, and the use of systemic corticosteroids; with hematopoietic malignancies[38]; and in the setting of human immunodeficiency virus infection.[39] Porokeratosis has also been reported after bone marrow transplantation in the absence of ongoing immunosuppressive therapy, which suggests a more complex association than immunosuppression alone.[40] The distribution and morphology of DSP of immunosuppression are similar to those of DASP, but a history of sun exposure is less evident.

Linear Porokeratosis

Linear porokeratosis is an uncommon variant that usually presents in early childhood, although congenital presenta-

▲ **FIGURE 50-2** **A.** Disseminated superficial actinic porokeratosis with multiple lesions on the forearm in this severely affected individual. **B.** The characteristic furrowing (*arrows*) is clearly demonstrated on the forearm of this patient.

▲ **FIGURE 50-3** Linear porokeratosis showing the characteristic distribution along Blaschko's lines.

tions have been reported.[41] Two distinct clinical variants have been described. The more common presentation consists of a unilateral lesion confined to an extremity following Blaschko's lines (Fig. 50-3). In the rare generalized form, multiple lesions affect several extremities and may involve the trunk. Linear porokeratosis is thought to represent a mosaic form of classic porokeratosis of Mibelli, resulting from a postzygotic mutation. Linear variants have the highest potential for malignant degeneration of all the porokeratoses. It has been postulated that this association can be attributed to allelic loss due to mutation or overexpression of p53.[42] There are also reports of the co-existence of linear porokeratosis and DSAP in the same patient or a first-degree family member.[43,44] These findings may be explained by the loss of heterozygosity for the DSAP allele and provides an example of the type 2 segmental manifestations of an autosomal dominant disorder.[45,46]

Porokeratosis Palmaris et Plantaris Disseminata

Porokeratosis palmaris et plantaris disseminata (porokeratosis punctata palmaris et plantaris) is a genodermatosis with an autosomal dominant inheritance pattern characterized by small, relatively uniform lesions (Fig. 50-4) that initially appear on the palms and soles. Subsequently, lesions spread to involve other parts of the body, including the mucous membranes and non–sun-exposed sites. The palmar and plantar lesions are generally more hyperkeratotic, and the characteristic longitudinal furrow along this ridge may be quite pronounced (Fig. 50-5). Typically the lesions appear in during adolescence or early adulthood and are bilateral and distributed symmetrically. Porokeratosis palmaris et plantaris disseminata affects males twice as often as females.

▲ **FIGURE 50-4** Porokeratosis palmaris et plantaris disseminata showing multiple superficial lesions on the calf. Note the similarity to disseminated superficial actinic porokeratosis shown in Fig. 50-2A.

Punctate Porokeratosis

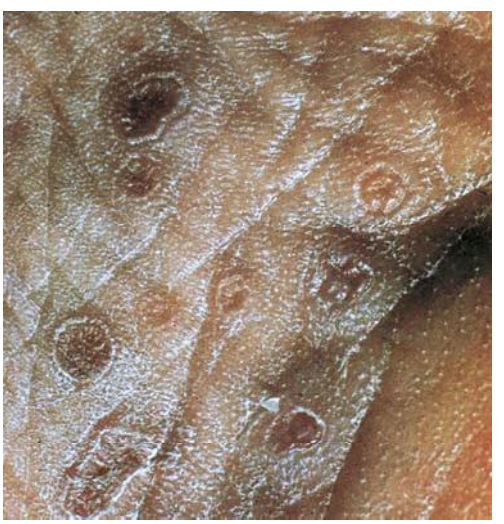
Punctate porokeratosis usually appears during adolescence or adulthood and may be seen concomitantly with other types of porokeratosis. Multiple minute and discrete punctate, hyperkeratotic lesions surrounded by a thin, raised margin are present on the palms and soles. Lesions may occur in a linear arrangement, or they may aggregate to form plaques. Punctate porokeratosis must be differentiated clinically and histologically from punctate keratoderma, also referred to as punctate porokeratotic keratoderma or as porokeratosis punctata palmaris et plantaris (see Chap. 48).

CDAGS Syndrome

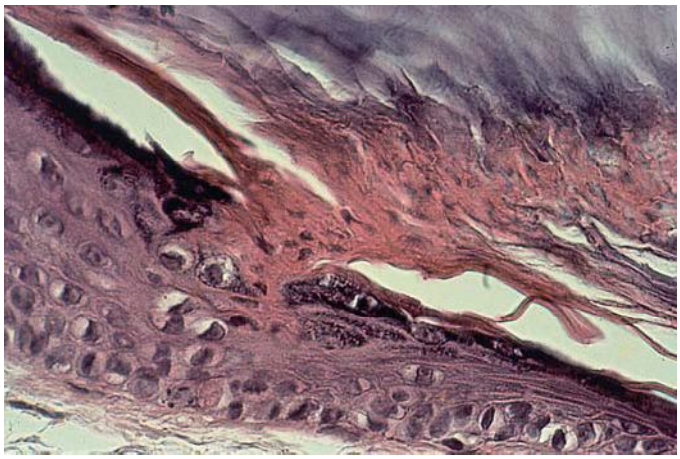
CDAGS syndrome (*c*raniosynostosis and clavicular hypoplasia, *d*elayed closure of the fontanel, *a*nal anomalies, *g*enitourinary malformations, *s*kin eruption), also referred to as *CAP syndrome* (*c*raniosynostosis, *a*nal anomalies, *and* p*o*rokeratosis), is a rare genodermatosis reported in four ethnically diverse families to date.[47,48] The main phenotypic features consist of craniosynostosis and clavicular hypoplasia, anal anomalies, and porokeratosis. It appears to segregate as an autosomal recessive trait, with possible linkage to chromosome band 22q12-13. The cutaneous manifestations are strikingly consistent, with the development of small, widespread porokeratotic papules from 1 month of age in affected individuals, predominantly affecting the face and extremities, with reported photoaggravation of lesions. It is postulated that dysregulation of multiple signaling pathways during embryogenesis is causative; however, no unifying pathogenetic mechanism has been identified.

HISTOPATHOLOGY

Histopathologic patterns are similar in all forms of porokeratosis, with the characteristic changes evident at the raised and advancing edge of the lesion. The stratum corneum is hyperkeratotic, with a thin column of poorly staining parakeratotic cells, the cornoid lamella, running through the surrounding normal-staining cells (Fig. 50-6). The underlying keratinocytes are edematous with spongiosis and shrunken nuclei, and a striking dermal lymphocytic pattern may be evident. Underlying the cornoid lamella, the granular layer is either absent or markedly reduced but is of nor-



◀ **FIGURE 50-5** Sole of the foot in a patient with porokeratosis palmaris et plantaris disseminata. The ridge and furrow are clearly seen.



▲ **FIGURE 50-6** The cornoid lamella arises from an indentation of the epidermis and extends as a thin column throughout the stratum corneum. The underlying granular layer is absent or reduced.

mal thickness in other areas of the lesion. The epidermis in the central portion of porokeratosis may be normal, hyperplastic, or atrophic. Although characteristic of porokeratosis, the cornoid lamella is not pathognomonic and may also be found in other conditions, such as viral warts, some ichthyoses, and nevoid hyperkeratoses.

DIFFERENTIAL DIAGNOSIS

The classic lesions of porokeratosis are clinically distinctive, and the diagnosis is usually clinically apparent. Atypical lesions, however, may require differentiation (Box 50-2). A cornoid lamella may be found in actinic keratoses but in actinic keratosis is distinguished by the presence of cytologic atypia. Verruca vulgaris often shows mounds of parakeratosis that are sometimes identical to cornoid lamellae, but koilocytosis is usually present. Linear porokeratosis may be clinically confused with other linear lesions, such as linear inflammatory verrucous epidermal nevus, incontinentia pigmenti (stage II), and lichen planus, none of which has a cornoid lamella.

Box 50-2

Differential Diagnosis of Porokeratosis

LOCALIZED LESIONS

Most Likely

- Granuloma annulare
- Tinea corporis
- Actinic keratosis
- Viral warts

Consider

- Elastosis perforans
- Lichen planus
- Goltz syndrome

LINEAR

Consider

- Linear inflammatory verrucous epidermal nevus
- Incontinentia pigmenti (stage II)
- Lichen planus
- Ichthyosis linearis circumflexa

TREATMENT

Lesions of porokeratosis are chronic, slowly progressive, and relatively asymptomatic, although intense pruritus has been reported.[49] Intervention is usually unnecessary, and disease surveillance is standard. If the lesions are problematic or cosmetically unacceptable, however, treatment with potent topical steroids, keratolytics, topical retinoids, topical 5-fluorouracil,[50] imiquimod 5 percent, calcipotriol,[51] anthralin,[52] cryotherapy,[53] carbon dioxide laser,[54] pulsed dye laser,[55] or neodymium:yttrium-aluminum-garnet laser may be considered (Box 50-3). Treatment outcomes are variable and treatments are poorly standardized. Ablative techniques, such as curettage, excision, and dermabrasion,[56] have also been used with variable degrees of success. Oral retinoids have been shown to give the most reproducible results, with reduction in the size and thickness of extensive lesions, although the disease typically recurs after their discontinuation. Given the association with malignancy, closer disease surveillance and a lower threshold for biopsy of suspicious lesions may be warranted in cases of giant porokeratoses and linear lesions, and in immunosuppressed individuals.

Box 50-3

Treatment for Porokeratosis

	TOPICAL	SURGICAL	SYSTEMIC
First line	Photoprotection 5-Fluorouracil	Cryotherapy	
Second line	Calcipotriol Imiquimod Topical corticosteroids Topical retinoids	CO_2 laser vaporization	Oral retinoids
Third line	Dermabrasion Neodymium:yttrium-aluminum-garnet laser Grenz ray	Surgical excision	

COURSE AND PROGNOSIS

The porokeratoses are generally chronic and progressive, with lesions increasing in size and number with time. Typically, this process occurs over decades in porokeratosis of Mibelli but may be rapid in DSAP, particularly after sun exposure. In cases of immunocompromise, fluctuations in severity may parallel the state of immunocompetence, and there are reports of remission after removal of primary malignancy.[30] The disease is generally considered a benign process; however, malignant degeneration may occur. Malignancy is thought to arise in 7 percent to 11 percent of individuals, although these figures are likely overestimated. Squamous cell carcinoma is the most frequently associated tumor and may be invasive. Bowen disease and basal cell carcinoma have also been reported. Spontaneous resolution of lesions has been reported, although it is exceptionally rare.[57]

SECTION 8

DISORDERS OF EPIDERMAL AND DERMAL-EPIDERMAL COHESION AND VESICULAR AND BULLOUS DISORDERS

CHAPTER 51

Epidermal and Epidermal-Dermal Cohesion

Leena Bruckner-Tuderman
John R. Stanley

The cell-cell and cell–basement membrane adhesion in the epidermis provides the skin with its resistance against environmental influences; epidermal integrity is required for protection of the entire organism against mechanical, physical, or microbial noxae. The major cellular structures involved are the desmosomes at cell-cell junctions in the epidermis and the hemidesmosome–basement membrane adhesion complexes and related structures at the epidermal-dermal junction. Ultrastructurally, the hemidesmosome closely resembles one-half of the desmosome; however, at the molecular level, these two structures are distinct. Both represent specifically organized assemblies of intracellular and transmembrane molecules, which on one hand anchor cytoskeletal filaments to the cell plasma membrane and on the other hand the plasma membrane to extracellular structures, i.e., another cell or the extracellular matrix. Our knowledge of the desmosomal, hemidesmosomal, and basement membrane molecules has expanded drastically in the last 10 to 15 years due to the great power of both molecular genetics and proteomics. After some of the proteins were initially identified as autoantigens in pemphigus and pemphigoid, a multitude of molecules have now been characterized at both protein and gene levels, and their expression, regulation, and functions have been discerned. The antigenic epitopes in different autoimmune blistering skin diseases have been carefully mapped and, to date, mutations in at least 18 different genes have been shown to underlie heritable disorders of epidermal or epidermal-dermal adhesion in humans and mice. Morphologic, molecular and functional aspects of these adhesion structures are delineated in this chapter.

EPIDERMAL COHESION

Ultrastructure of Desmosomes

Desmosomes (also called *maculae adhaerentes*) are the major cell adhesion junction of epithelial tissues; however, they are also found in myocardium and a few other tissues.[1–3] Not only do they serve as a sort of spot weld of the keratinocytes but they also anchor intermediate filaments (keratin in the case of epidermis and mucous membranes) to the cell surface. In serving these functions, they form a three-dimensional scaffolding of the intermediate filaments that are stretched from the nuclear envelope to the cell surface.[4] This scaffolding is critical to stabilize epidermal structure in the face of external trauma, and its collapse results in cytolysis of keratinocytes (see Chaps. 47 and 60).

Ultrastructural cross-section of the desmosome shows a symmetric structure consisting of two apposing dense plaques inside the membranes that are themselves separated by approximately 30 nm (Fig. 51-1A).[5] This intercellular center has been called the *desmoglea* (from Greek, "desmosomal glue"), because it is thought to provide the adhesion that keeps cells together at this junction.[6] In high resolution, there is a thin electron dense midline in the center of the desmoglea. The dense plaque inside the cell actually is formed of an outer very dense plaque bordering the membrane, and an inner less dense plaque that intertwines with keratin intermediate filaments.

Biochemical Characterization of Desmosomes

The molecular components of the various desmosomal substructures have been biochemically characterized and cloned (see Fig. 51-1B).[4] These proteins fall into three major gene families: plakins (e.g., desmoplakin), armadillo proteins (e.g., plakoglobin and plakophilins), and desmosomal cadherins (desmogleins and desmocollins). Plakins and armadillo proteins are in the plaque, and desmosomal cadherins are transmembrane proteins whose extracellular amino-termini comprise the desmoglea. The major inner plaque component is *desmoplakin*, which exists in two RNA splice variants, desmoplakin I and II.[7,8] Desmoplakin is part of the plakin gene family,[9] which includes bullous pemphigoid antigen 1 and plectin, plaque proteins of the hemidesmosome, as well as envoplakin and periplakin, whose functions in the desmosome are not as yet well defined. Similar to other desmosomal components, desmoplakin is a modular protein, with different modules fulfilling different functions. The central part of one desmoplakin molecule coils around the central part of another to form a rod-like center. The carboxy-terminus binds to keratin filaments,[10] and the amino terminus binds to plakoglobin.[11] Desmoplakin, therefore, provides the major link between the keratin filaments and the desmosomal plaque.

Plakoglobin is the second major protein in desmosomal plaques.[12] A member of the armadillo gene family that also includes plakophilins,[13] it is a modular protein with repeating homologous units.

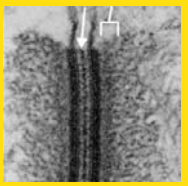
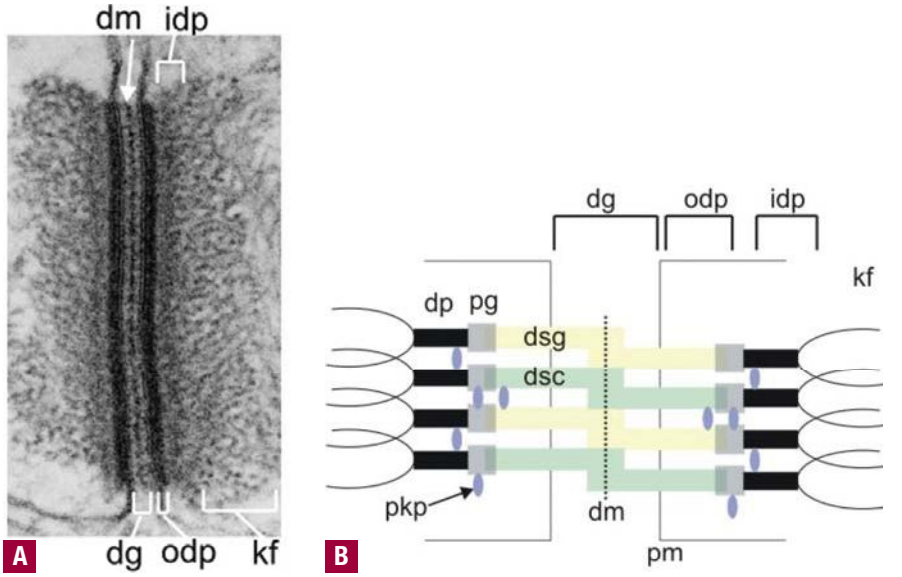
EPIDERMAL AND EPIDERMAL-DERMAL COHESION

AT A GLANCE



- Desmosomes, hemidesmosomes, and the epidermal basement membrane are providers of epidermal and epidermal-dermal cohesion.
- They represent distinct molecular adhesion complexes.
- The major components of desmosomes belong to three major gene families: the plakins, armadillo proteins, and desmosomal cadherins.
- The hemidesmosomal components comprise plakin homologues, integrins, and collagenous transmembrane proteins.
- All basement membranes contain collagen IV, laminins, nidogens, and perlecan.
- Functional specificity of basement membranes is provided by additional tissue-specific glycoproteins.
- In addition to their structural roles, desmosomes, hemidesmosomes, and the epidermal basement membrane are biologically active in cellular signaling.
- Mutations in the genes encoding the above proteins cause hereditary skin diseases; ranging from hypotrichosis and keratoderma to epidermolysis bullosa and Kindler syndrome.
- Protein components of desmosomes, hemidesmosomes, and epidermal basement membrane are targeted in autoimmune skin blistering diseases of the pemphigus or pemphigoid group and in epidermolysis bullosa acquisita.



▲ **FIGURE 51-1** Electron microscopic image (**A**) and simplified schematic diagram (**B**) of a desmosome (not drawn to scale). dg = desmoglea; dm = dense midline; dp = desmoplakin; dsc = desmocollins; dsg = desmoglein; idp = inner dense plaque; kf = keratin filaments; odp = outer dense plaque; pg = plakoglobin; pkp = plakophilins; pm = plasma membrane. (Electron micrograph used with permission from Kathleen Green and with permission of Elsevier, adopted from Yin T, Green KJ: Regulation of desmosome assembly and adhesion. *Semin Cell Develop Biol* **15**:665, 2004.)

The first indication of plakoglobin binding to a desmosomal protein (desmoglein) came from studies with pemphigus (see Chap. 52) sera in which plakoglobin was co-precipitated with desmoglein by both pemphigus vulgaris and foliaceus sera.[14] *Desmoglein* 3 and 1 are the pemphigus vulgaris and foliaceus antigens, respectively, that the sera bound, and plakoglobin was co-precipitated because of its binding to these desmogleins. Various domains of plakoglobin modulate its binding to desmogleins and desmocollins.[15–17] Other domains bind to desmoplakin, thus linking desmogleins and desmocollins to desmoplakin.[11] *Plakophilins*, additional plakin proteins in the desmosome, bind various desmosomal components, and may aid in clustering and stabilizing them.[18,19]

Finally, desmogleins and desmocollins provide the link between the extracellular desmoglea and the intracellular plaque.[20–22] These glycoproteins are in the cadherin supergene family, and, similar to other members of this family, are thought to mediate calcium-dependent adhesion. In humans, there are four genes encoding desmogleins 1, 2, 3, and 4. The desmoglein 3 gene was actually discovered and cloned because it was the antigen in pemphigus vulgaris (see Chap. 52).[23] These isoforms have different tissue distributions with desmogleins 1 and 3 being predominant in epidermis and mucous membranes. Within these tissues, the desmogleins also have unique distributions, which has major implications for understanding the pathophysiology of pemphigus (see Chap. 52). Similarly, there are four genes encoding desmocollins I, II, III, and IV, which in addition have alternative RNA splice variants, and, similar to desmogleins, each have unique tissue specific distributions.[21,24–26] These desmosomal cadherins play a major role in providing cell adhesion in the epidermis and mucous membranes. Similar to the other desmosomal components, desmosomal glycoproteins are modular with different parts of the molecules providing different functions. Their cytoplasmic tails bind plakoglobin and other armadillo proteins and their extracellular domains provide adhesion with desmosomal cadherins expressed on apposing cells.

Function and Pathology of Desmosomes

As described in Biochemical Characterization of Desmosomes, the major function of desmosomes is thought to be cell adhesion. Animal models, autoimmune skin diseases, and the blisters caused by exfoliative toxin from staphylococci confirm this function (Table 51-1; see Chaps. 52 and 178).[27] For example, a mouse genetically engineered with a targeted deletion of desmoglein 3 develops mucous membrane and skin blisters from loss of cell adhesion in the deep epidermis, similar to pemphigus vulgaris patients.[28] Patients with pemphigus vulgaris and foliaceus develop loss of cell adhesion and resultant blisters in the epidermis due to anti-desmoglein 3 and 1 antibodies, respectively (Fig. 51-2).

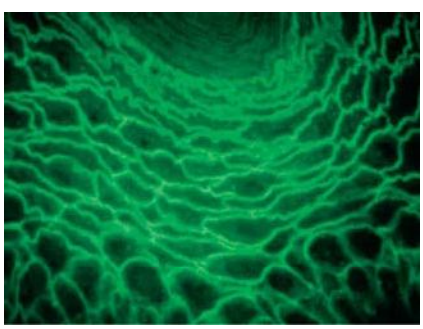
TABLE 51-1
Desmosomal Targets in Skin Disease

	Desmosome Component	Autoimmune Target	Genetic Target
Desmosomal cadherins	Desmoglein 1[a]	PF	SPPK (AD)
	Desmoglein 3	PV, PNP	
	Desmoglein 4	PF,[b] PV[b]	AR hypotrichosis
	Desmocollins	SPD[47]	
Desmosomal plaque proteins	Desmoplakin	PNP	SPPK (AD); keratoderma, woolly hair, left ventricular cardiomyopathy (AR)
	Other plakins[c]	PNP	
	Plakoglobin		Naxos disease: keratoderma, woolly hair, right ventricular cardiomyopathy (AR)
	Plakophilins		Plakophilin 1: skin fragility and ectodermal dysplasia (AR)
Stratum corneum desmosome protein	Corneodesmosin		Hypotrichosis simplex of the scalp (AD)[47]

[a]Also targeted by exfoliative toxin in bullous impetigo and staphylococcal scalded-skin syndrome.
[b]Anti-desmoglein 1 in these sera cross-react with desmoglein 4.
[c]Including envoplakin, periplakin, and bullous pemphigoid antigen 1.
AD = autosomal dominant; AR = autosomal recessive; PF = pemphigus foliaceus (see Chap. 52); PNP = paraneoplastic pemphigus (see Chap. 53); PV = pemphigus vulgaris (see Chap. 52); SPD = subcorneal pustular dermatosis (see Chap. 34); SPPK = striate palmoplantar keratoderma (see Chap. 48).

Exfoliative toxins from staphylococci specifically cleave desmoglein 1 to cause blisters from loss of cell adhesion in the superficial epidermis in bullous impetigo and staphylococcal scalded skin syndrome (see Chap. 178).[29]

More recent data suggests that the function of desmosomes is much more complicated than simple cell adhesion. For example, desmosomal molecules are important in development and differentiation.[30,31] A targeted genetic deletion of desmoglein 2 causes early embryonic lethality in mice, and prevents proliferation of embryonic stem cells.[32] Inappropriate expression of desmoglein 3 in the upper epidermis results in hyperproliferation, abnormal differentiation, and barrier defects.[33,34] Mice with a targeted deletion of desmocollin I also have abnormal differentiation and a defective epidermal barrier.[35] In addition, the armadillo components of the desmosome may mediate or modulate signal transduction.[31] The original member of the armadillo family, *Armadillo*, was discovered in Drosophila as a member of the Wnt signaling pathway. Another member of the family, β-catenin, is both a component of the adherens junction, another cell adhesion junction, and plays a critical role in Wnt signaling in epithelial cells. β-Catenin, in this later function, translocates to the nucleus and complexes with other molecules to form a transcription factor. Plakoglobin, a member of this family, may also serve a similar dual role (adhesion and signaling), but exactly how remains to be determined. Similarly, plakophilins may localize to both desmosomes and translocate to the nucleus, suggesting they also may be involved in signaling and transcription.[36–38]



▲ **FIGURE 51-2** Indirect immunofluorescence staining of human epidermis with pemphigus serum that contains autoantibodies to desmoglein 3.

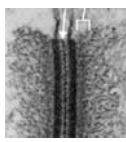
These complexities of the function of desmosomal components may account for the various disease manifestations of patients with mutations in desmosome genes (see Table 51-1).[39,40] Desmoglein 1 and desmoplakin mutations are associated with striate palmar plantar keratoderma.[41,42] Desmoglein 4 mutations are found in autosomal recessive hypotrichosis.[43] Autosomal recessive desmoplakin mutations can cause not only keratoderma but woolly hair and left ventricular cardiomyopathy.[44] Plakoglobin mutations result in Naxos disease, keratoderma, woolly hair, and arrhythmogenic right ventricular cardiomyopathy.[45] Plakophilin 1 mutations result in a disease that includes skin fragility and ectodermal dysplasia.[46] Interestingly, some of these genetic diseases of different desmosomal components have overlapping clinical features, suggesting that they may share certain final common pathophysiologic pathways.

The exact pathophysiologic mechanisms relating the mutations in these genetic diseases to the phenotypes have not been well worked out. However, these diseases clearly indicate the importance of desmosomes and their components beyond just cell adhesion.

EPIDERMAL-DERMAL COHESION

Structural and Functional Characteristics of Basement Membranes

Basement membranes underlie epithelial and endothelial cells and separate them from each other or from the adjacent stroma. Another form of basement membrane surrounds smooth muscle or nerve cells. The physiologic functions of basement membranes are diverse: In the various organ systems they provide support for differentiated cells, maintain tissue architecture during remodeling and repair, and, in some cases, acquire specialized functions, including the ability to serve as selective permeability barriers (e.g., the glomerular basement membrane or the blood-brain barrier) or acquire strong adhesive properties, like the basement membrane at the dermal-epidermal junction, or that surrounding smooth muscle cells, which provide the tissues resistance against shearing forces. All of these characteristics of basement membranes are also used during development and differentiation of multicellular organisms (Box 51-1).



Box 51-1

Major Functions of Basement Membranes

- Scaffold for tissue organization and template for tissue repair.
- Selective permeability barriers. The renal basement membranes serve for the ultrafiltration of plasma, and other basement membranes also demonstrate selective filtration.
- Physical barriers between different types of cells or between cells and their underlying extracellular matrix.
- Firmly link an epithelium to its underlying matrix or to another cell layer and provide polarity.
- Regulate cellular functions.

Ultrastructurally, basement membranes most often appear as trilaminar structures, consisting of a central electron-dense region, known as the *lamina densa*, adjacent on either side to an apparently less-dense area, known as the *lamina lucida* or *lamina rara*. The lamina lucida directly abuts the plasma membranes of the adherent cells. The relative size of each of these regions varies among basement membranes of different tissues, among the basement membranes of the same tissue at different ages, and as a consequence of diseases. For example, the trilaminar glomerular basement membrane in humans varies from 240 nm to 340 nm in width, whereas the bilaminar basement membrane of the dermal-epidermal junction measures 50 nm to 90 nm. This ultrastructure demonstrates that basement membranes serve as substrates for the attachment of cells and fix their polarity. Their continuity throughout the various organ systems stabilizes the established tissue orientations and provides a template for orderly repair after traumatic injury. Major disruptions in the basement membrane result in the formation of scar tissue and the loss of function in that area.

Different basement membranes contain both common and unique components. All share a basic network structure to which specific macromolecules have been appended. These molecules are responsible for the specialized structures and functions of different basement membranes. The basic constituents of these structures are collagen IV, laminins, nidogens, and proteoglycans of the perlecan type, which all are highly conserved, although the isoforms, the number of the polypeptide subunits, and their individual structures vary among species.[47,48] The nearly ubiquitous distribution of heparan sulfate proteoglycans in all basement membranes suggests that these serve as selective permeability barriers in multiple locations, including the kidney and the blood-brain barrier. Ultrafiltration may be especially important during development and morphogenesis of all tissues.

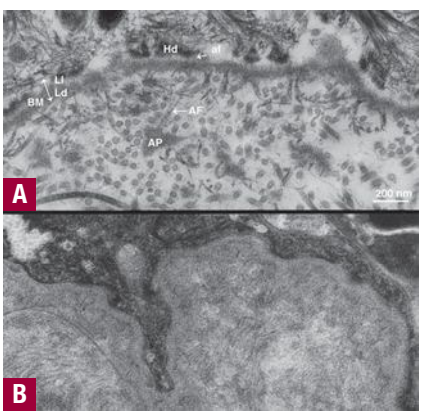
Basement membranes also provide physical separation between epithelia and their underlying extracellular matrices. This barrier is especially important in the containment of tumors. With the exception of certain cells of the immune system, non-malignant cells seldom cross a basement membrane. Benign tumor cells, when placed on isolated amniotic basement membranes, are unable to cross this barrier in vitro. In contrast, malignant cells bind the basement membrane, regionally disrupt its structure at the site of the attachment, and migrate through the rupture. Laminins and integrins mediate the tumor-cell binding, and the basement membrane dissolution is catalyzed by metalloproteases produced by the tumor cell. The absence of distinguishable basement membranes in tumor biopsies has been an indicator of malignancy, and there appears to be a high correlation between metastasis and basement membrane degradation. These observations underline the importance of the basal lamina as an obstacle to cell migration.

By binding biologically active signaling molecules, basement membranes regulate a multitude of biologic events. The constituent proteoglycans can bind growth factors that can be released from the complexes by tissue proteinases. Thus, the basement membranes are potent regulators of cell adhesion and migration, cytoskeleton and cell form, cell division, differentiation and polarization, and apoptosis.[49]

ULTRASTRUCTURE OF THE DERMAL-EPIDERMAL JUNCTION

The dermal-epidermal junction is an example of a highly complex form of basement membrane,[50,51] which underlies the basal cells and extends into the upper layers of the dermis (Fig. 51-3A). This basement membrane is continuous along the epidermis and skin appendages, including sweat glands, hair follicles, and sebaceous glands. The dermal-epidermal junction can be divided into three distinct zones. The first zone contains the keratin filament-hemidesmosome complex of the basal cells and extends through the lamina lucida to the lamina densa. The plasma membranes of the basal cells in this region contain numerous electron-dense plates known as hemidesmosomes. The intracellular architecture and organization of the basal cells are maintained by keratin intermediate filaments, 7 to 10 nm in diameter that course through the basal cells and insert into the desmosomes and hemidesmosomes. External to the plasma membrane is a 25- to 50-nm–wide lamina lucida that contains anchoring filaments, 2 to 8 nm in diameter, originating in the plasma membrane and inserting into the lamina densa. The anchoring filaments can be seen throughout the lamina lucida but they are concentrated in the regions of the hemidesmosomes. Ultrastructurally, the anchoring filaments appear to secure the epithelial cells to the lamina densa.

The existence of the lamina lucida in vivo has been questioned. When the ultrastructure of the basement membrane is evaluated after high-pressure preservation techniques, the lamina densa ap-



▲ **FIGURE 51-3** **A.** Ultrastructure of the human dermal-epidermal junction as visualized by transmission electron microscopy after standard fixation and embedding protocols. af = anchoring filament; AF = anchoring fibril; AP = anchoring plaque; BM = basement membrane; Hd = hemidesmosome; Ld = lamina densa; Ll = lamina lucida. (Bar = 200 nm.) **B.** Ultrastructure of the human dermal-epidermal junction by transmission electron microscopy following protocols using high-pressure fixation and embedding techniques. Note the dense character of both the basement membrane and the subjacent papillary dermis. Anchoring filaments, anchoring fibrils, and anchoring plaques are not distinguishable. (Both photos used with permission from Douglas R. Keene, MD, Shriners Hospital, Portland, Oregon.)

pears intimately associated with the epithelial cell surface.[50,52] When the dermal-epidermal junction is similarly prepared, no distinct lamina lucida is seen (see Fig. 51-3B). This suggests that the lamina lucida may result from shrinkage of the cell surface away from the lamina densa due to dehydration. The appearance of anchoring filaments spanning the lamina lucida may then result from the firm attachment of constituents of the lamina densa at the hemidesmosome that is subsequently pulled from the lamina densa by shrinkage. Other components that are also tightly fixed to the keratinocyte plasma membrane, either at the hemidesmosomes or at other sites along the membrane between the hemidesmosomes, may similarly become displaced into the shrinkage space. Regardless of its actual occurrence in vivo, the evaluation of the lamina lucida by standard electron microscopy techniques has allowed identification of specific structures that would otherwise have been difficult to detect. In addition, the morphologic term *lamina lucida* remains practical in the scientific communication and continues to be used.

The second zone, the lamina densa, appears as an electron-dense amorphous structure 20 nm to 50 nm in width. The dermal-epidermal lamina densa is similar in appearance to analogous structures in other organs. At high magnification, it has a granular-fibrous appearance.[50] The major molecular components of the lamina densa are collagen IV, nidogen-entactin, perlecan, and laminins, which all can polymerize to networks of variable thickness.[53]

The subbasal lamina contains microfibrillar structures. Two of these are readily distinguishable. The first structure, known as *anchoring fibrils*, appears as condensed fibrous aggregates 20 nm to 75 nm in diameter.[54] At high resolution, they appear to have a nonperiodic cross-striated banding pattern (see Fig. 51-3A). The length of the anchoring fibril is difficult to measure because of its random orientation in relation to the plane of the section. In toad skin, these structures have lengths of approximately 800 nm. The anchoring fibrils in human skin appear to be somewhat shorter. The ends of the anchoring fibrils appear less tightly packed, giving a somewhat frayed appearance. The proximal end inserts into the basal lamina, and the distal end is integrated into the fibrous network of the dermis.[55] Many of the anchoring fibrils originating at the lamina densa loop back into the lamina densa in a horseshoe-like manner; others insert their opposite ends into amorphous-appearing structures, termed *anchoring plaques*.[55] These structures are believed to be independent "islands" of electron-dense material, although some controversy exists in the literature.[56] Anchoring fibrils are primarily aggregates of collagen VII.[57]

Tubular fibrillin-containing microfibrils, 10 nm to 12 nm in diameter, are also localized in the sublamina densa region. These are elastic-related fibers, because elastic components of the dermis are formed from microfibrillar and amorphous components.[58] The microfibrillar component in the presence of abundant amorphous component is known as the *elastic fiber*. In the papillary dermis, the microfibrils insert into the basal lamina perpendicular to the basement membrane and extend into the dermis, where they gradually merge with the elastic fibers to form a plexus parallel to the dermal-epidermal junction. These two elastic components appear to be continuous with the elastic fibers present deep within the reticular dermis.[58] The gradient of an increasing amorphous component from the basal lamina into the reticular dermis may represent a system of increasingly mature elastic fibers.

In summary, the ultrastructure of the dermal-epidermal junction strongly suggests that the lamina densa functions as a structural scaffold for the attachment of the epidermal cells at one surface, secured by anchoring filaments extending from the lamina densa to the hemidesmosomes. The latter also serve as insertion points for intracellular keratin filaments that form scaffolding for the basal cells. On the opposite surface, the extracellular matrix suprastructures of the dermis are firmly attached to the lamina densa. The interaction of different dermal fibers with the basal lamina appears to be mediated by the anchoring fibrils. The elastic system of the dermis inserts directly into the basal lamina via the microfibrils. Thus, the dermal-epidermal junction provides a continuous series of attachments between the reticular dermis and the cytoskeleton of the basal cells. These observations suggest four major functions for the epidermal basement membrane: (1) a structural foundation for the secure attachment and polarity of the epidermal basal cells; (2) a barrier function, separating the components of the epidermis and the dermis; (3) firm attachment of the dermis to the epidermis through a continuous system of structural elements; and (4) modification of cellular functions, such as organization of the cytoskeleton, differentiation, or rescue from apoptotic signaling via outside-in signalling mechanisms.

Ubiquitous Components of Basement Membranes

- Collagen IV
- Laminins
- Nidogens
- Perlecan

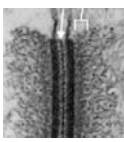
BIOCHEMICAL CHARACTERIZATION OF THE BASEMENT MEMBRANE

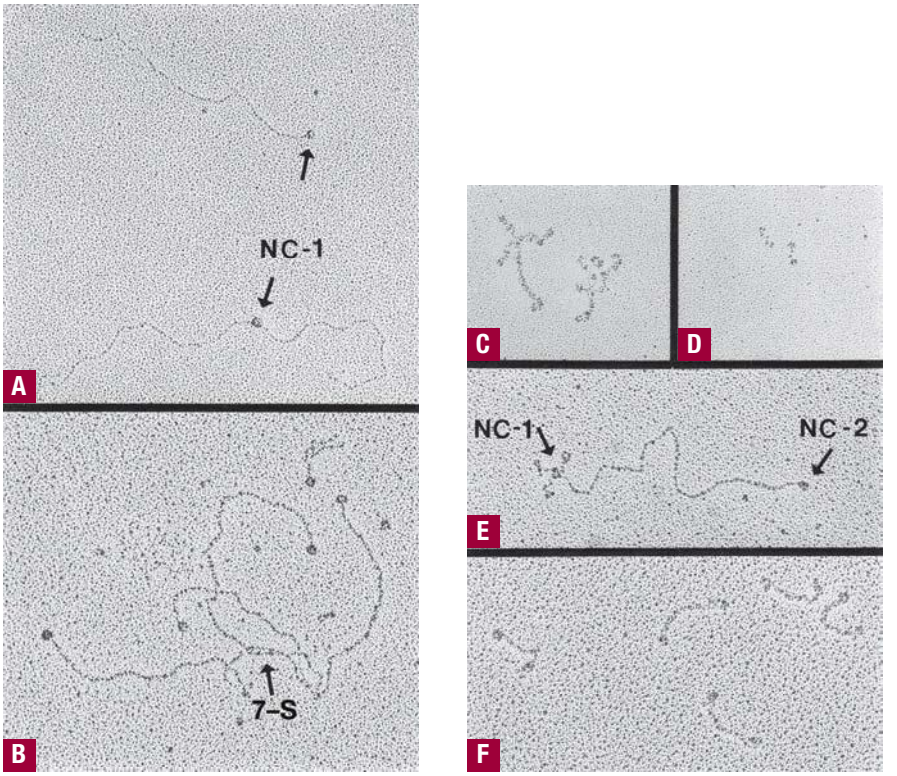
Basement membranes contain collagenous and non-collagenous glycoproteins and proteoglycans. The unusual amino acids hydroxyproline and hydroxylysine are found almost exclusively in collagens;[59] the hydroxyproline content suggests that collagens account for 40 percent to 65 percent of the total basement membrane protein. All basement membranes contain collagen IV as the major collagen, laminin, nidogen, and the heparan sulfate proteoglycan perlecan, irrespective of tissue source (Box 51-2). In addition, many other tissue specific glycoproteins have been found in basement membranes, including different laminins, fibulins, and fibronectin.[47–49]

In contrast to the ubiquitous components within all basement membranes, some molecules demonstrate a restricted distribution. Certain collagen IV isoforms, collagens VII and XVII, or several laminins, are not ubiquitous. For example, the α3 chain of collagen IV is localized in the basement membrane of the kidney and lung, but not in those of the skin and blood vessels. In contrast, collagens VII and XVII are associated with the squamous epithelia of skin but are not found in glomerular and alveolar basement membranes. Differences in macromolecular composition are responsible for morphologic and functional variance of basement membranes.

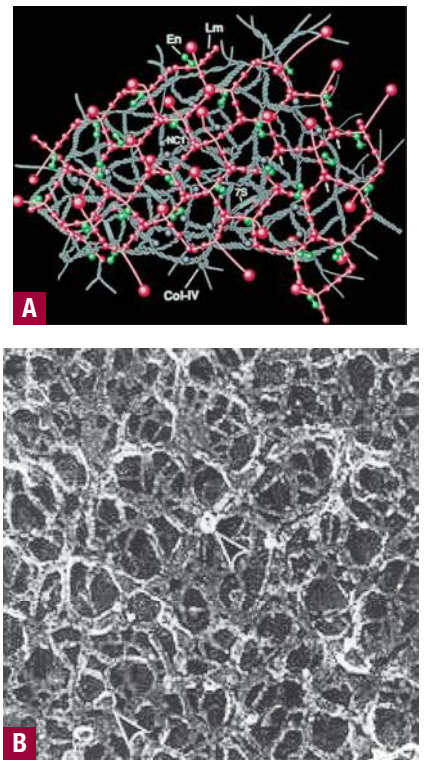
Ubiquitous Components of Basement Membranes

COLLAGEN IV Collagen IV is a heterotrimer of three α chains.[48,59] Each of these contains three distinct domains (Fig. 51-4A): the N-terminal cysteine-rich (7-S)





▲ **FIGURE 51-4** Images of basement membrane molecules visualized by rotary shadowing. **A.** Collagen IV monomer and a dimer resulting from aggregation of C-terminal NC-1 domains. **B.** Collagen IV tetramer ("spider") demonstrating the 7-S domain with the four protruding molecules and their large terminal NC-1 domains. **C.** Laminin 1 (laminin 111) molecules. **D.** Nidogen molecules. **E.** Procollagen VII. The NC-1 and NC-2 regions are indicated. **F.** Laminin 5 (laminin 332) molecules. (All micrographs were provided by Douglas R. Keene, MD, Shriners Hospital, Portland, Oregon.)



▲ **FIGURE 51-5** **A.** Representation of the networks formed by the ubiquitous components of the basement membranes. Monomeric collagen IV (Col-IV) self-assembles into dimers and tetramers that further aggregate into a complex lattice. Laminins self-polymerize into networks. Perlecan can oligomerize in vitro, and the glycosaminoglycan side chains interact with the Col-IV framework. Nidogen-entactin is thought to bind components of all three networks and also fibulins. Nidogen therefore plays a central role as a stabilizer of the lamina densa framework. Individual molecules are not drawn to scale. (Drawing used with permission from Peter Yurchenco, MD, Robert Wood Johnson Medical School, Piscataway, N.J, U.S.A.) **B.** Rotary shadowing image of a quick-freeze, deep-etch replica of Col-IV polymers. The replica shows an extensive, branching and anastomosing network with occasional globular structures (*arrowhead*), which can be visualized as a model for the structure of the lamina densa. domain, a central triple-helical domain, and a C-terminal globular domain (NC-l). The trimer composition is determined by the NC-l domains, and the α chains are linked to each other by covalent interactions through these domains.[60] The triple helix of collagen IV is long and contains several sites at which glycine is not present in every third position.[59] These discontinuities result in increased flexibility in the collagen IV helix, but also render it susceptible to a variety of proteases.

The characteristic fibril structure of the interstitial collagens results from aggregation of molecules in a staggered array, producing a cross-banding pattern in electron microscope after appropriate staining. In contrast, the ultrastructure of the lamina densa indicates no periodic cross-striations, suggesting that the aggregates of collagen IV are different. The suprastructure of collagen IV has been partially elucidated by rotary shadowing electron microscopy that indicated that the major interactions among collagen IV molecules occur at their amino- and carboxyl-terminal domains, and by lateral association of their triple helices (see Fig. 51-4A).[47,48,59] Covalent interactions among 7-S regions of different molecules are the basis for the specialized network characteristic of basement membranes (see Fig. 51-4B). The individual 7-S regions overlap in both the parallel and antiparallel directions, producing a characteristic four-legged "spider" form. The NC-l domains at the end of each leg of the spider interact with the NC-l domain of the adjacent aggregates (see Fig. 51-4B). Association is stabilized by covalent bonds. These end-to-end interactions result in an extended two-dimensional network that is the basis of basement membrane organization.

The high flexibility of the basement membrane network structure makes the possibility of interactions with other collagens or noncollagenous molecules very attractive. An open meshwork of collagen IV with, for example, laminins or perlecan, can be easily visualized (Fig. 51-5).[49] The implied porosity of this structure would then be limited by the size of the pores in the collagen network and by structural elements associated with it. This model of the basement membrane structure allows considerable mechanical stability while retaining physiologic flexibility. These properties of strength and elasticity would be expected for a dynamic surface, such as that seen in the epidermal-dermal junction and surrounding blood vessels.

Collagen IV molecules in different basement membranes contain genetically distinct but structurally homologous

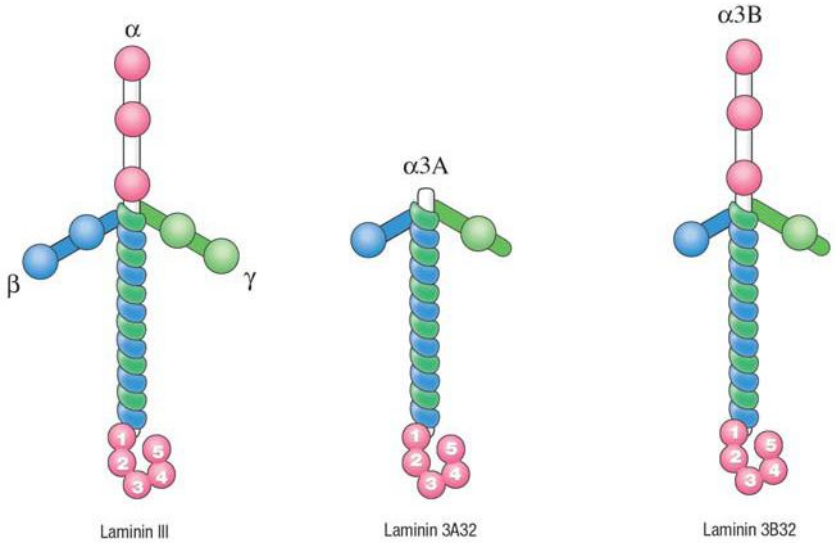
α chains. The α1 and α2 chains are ubiquitous, but the α3, α4, α5, and α6 chains show restricted distribution among tissues.[61] The chain organization and discriminatory interactions between the NC-1 domains govern network assembly in the basement membranes.[60] Two networks, namely α1-α2–containing and α3-α4-α5–containing networks, exist in the glomerular basement membrane. Smooth muscle basement membranes have an α1-α2-α5-α6–containing network in addition to the classic α1-α2 network. In the skin, the α1-α2–containing collagen IV network dominates within the dermal-epidermal junction, but α1-α2-α5-α6–containing network is also likely to be present.[62] Taken together, the six chains of collagen IV are distributed in three major networks, α1-α2, α3-α4-α5, and α1-α2-α5-α6, whose chain composition is determined by the NC-l domains.

The α3(IV) chain is the antigen recognized by the circulating autoantibodies in the Goodpasture syndrome,[61] and autoantibodies directed against the NC-l domain of the α5(IV) collagen chain were reported in a case with sub-epidermal bullous eruptions and renal insufficiency.[63] Structural aberrations in the genes encoding the α3, α4, α5, and α6 chains cause different forms of Alport syndrome, a genetic disease characterized by nephritis and deafness.[61] Recent analyses of mouse mutants revealed unexpected phenotypes of mutations in the mouse *Col4α1* and *Col4α2* genes encoding the α1 and α2 chains (i.e., abnormalities of the kidney, the brain, and the eye). Peripheral glomerulopathy in the kidney, porencephaly, a rare neurologic disease characterized by degenerative cavities in the brain, intracerebral hemorrhages, and a spectrum of eye abnormalities affecting the iris, cornea, retinal arterioles, and optic nerve were observed.[64,65] Subsequently, a *Col4α1* mutation was identified in a human family with small-vessel disease, which often underlies ischemic strokes and intracerebral hemorrhages.[66] Interestingly, despite the ubiquitous presence of the α1 and α2 chains of collagen IV in basement membranes, aberrations did not occur in all basement membranes, suggesting varying roles for collagen IV in different basement membranes.

Laminins. Laminins are very large glycoproteins (600 to 950 kd) within the lamina lucida/lamina densa of all basement membranes.[49] Three types of subunit chains have been designated α (200 kd to 400 kd), β (220 kd), and γ (155 kd to 200 kd) chains, and each laminin is a trimeric aggregate of one α, β, and γ chain. The trimers have semirigid and extended structures, which appear as an asymmetric cross in rotary shadowing electron microscopy (see Fig. 51-4C). The long arm of the cross is approximately 125 nm in length; the short arms are variable. Each laminin molecule is divided into globular and rod-like domains that have been individually implicated in various functions, such as aggregation with itself and with other components of the lamina densa (Fig. 51-6), cell attachment and spreading, neurite outgrowth, or cellular differentiation.[49,67] The C-terminal LG domain of the α chain, at the foot of the long arm of the laminin cross, harbors the binding site for integrins.[49,67]

To date, 15 laminin isoforms have been identified. These represent different trimeric combinations of five distinct α chains, three β chains and three γ chains known so far. Historically, laminins were named as *laminin-1* to *laminin-15*, in the order of their discovery, but this classification had grown quite impractical, with the need to memorize the numbers. A new, simplified nomenclature is based on the chain composition and the number of each α, β, and γ chain (Table 51-2).[68] For example, the classic "prototype" laminin-1, with α chain composition α1β1γ1, is now called *laminin 111*. The major laminin of the epidermal basement membrane, the previous laminin-5, with α chain composition α3β3γ2, is now called *laminin 332*.

The α2 chain containing laminins are present primarily within the basement membranes of the muscle fibers, nerves, neuromuscular junction, and glomerulus. Mutations in the α2 chain cause progressive muscular dystrophy and a significant decrease in the amount of basement membrane accumulated surrounding muscle cells.[67] The absence of the basement membrane leads to progressive degeneration of the muscle due to cell death. Therefore, the prediction is that laminins, and basement membranes in general, are required to prevent apoptosis by the cell types they surround.[67] The α3 chain is involved in epithelial adhesion (see Epithelial-Specific Basement Membrane Components), and the α4 and α5 chains are found in a variety of tissues including endothelia, epithelia, neuromuscular junction, and glomerulus.[69] Laminin 511 is present in the basement membrane of the epidermis and the hair follicles, where it is believed to be involved in developmental signaling.[70] The distribution of the β2 chain is largely restricted to the neuromuscular junction, but it is also found in nonmuscle tissues such as



▲ **FIGURE 51-6** A schematic representation of laminin molecules. Each laminin is a heterotrimer of an α, a β, and a γ chain. On the left, the classic prototype laminin 111 consisting of α1β1γ1 chains is shown. The N-terminal short arm of each chain is free, the long C-termini fold to a coiled-coil and form the long arm. The distal C-terminus of the α chain contains five globular LG domains, which harbor the integrin-binding site. Laminin 332, the previous laminin 5, exists in two forms, 3A32 and 3B32. These represent splice variants of the α chain, the short variant is 3A and the "full length" chain 3B. The N-termini of the β3 and γ2 chains are proteolytically processed to yield mature laminin 332.

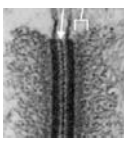


TABLE 51-2
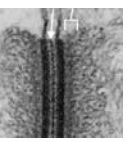
New Laminin Nomenclature[a]

Old Name	Chain Composition	New Name	Tissue Distribution
Laminin-1	α1β1γ1	Laminin 111	Developing epithelia
Laminin-2	α2β1γ1	Laminin 211	Muscle, nerves
Laminin-3	α1β2γ1	Laminin 121	Myotendinous junction
Laminin-4	α2β2γ1	Laminin 221	Neuromuscular junction, glomerulus
Laminin-5	α3β3γ2	Laminin 332A	Stratified epithelia
Laminin-6	α3β1γ1	Laminin 311A	Stratified epithelia
Laminin-7	α3β2γ1	Laminin 321A	Amnion, maybe other stratified epithelia
Laminin-8	α4β1γ1	Laminin 411	Endothelia, nerves, smooth muscle, adipose tissue
Laminin-9	α4β2γ1	Laminin 421	Endothelia, neuromuscular junction, smooth muscle, glomerulus, adipose tissue
Laminin-10	α5β1γ1	Laminin 511	Mature epithelia and endothelia, smooth muscle
Laminin-11	α5β2γ1	Laminin 521	Mature epithelia and endothelia, smooth muscle, neuromuscular junction, glomerulus
Laminin-12	α2β1γ3	Laminin 213	Muscle
Laminin-14	α4β2γ3	Laminin 423	Retina, central nervous system, kidney, testis
Laminin-15	α5β2γ3	Laminin 523	Retina, central nervous system, muscle, kidney

[a]See references 68 and 69.



the kidney glomerulus and the capillary basal lamina.[67] The β3 chain is involved in epithelial adhesion (see Epithelial-Specific Basement Membrane Components). Three γ chain variants—γ1, γ2, and γ3—are known. The γ2 chain is found only in laminin 332 in the skin (see Epithelial-Specific Basement Membrane Components). The γ3 chain, a component of laminins 423 and 523, binds nidogens 1 and 2 and is localized in basement membrane zones of adult and embryonic brain, kidney, skin, muscle, and testis. It is present in much lower concentrations than the γ1 chain, a fact that may indicate highly specialized functions.[71] The functions of all laminins are not yet fully understood, but by interacting with integrins and other cell surface components laminins control cellular activities such as adhesion, migration, proliferation, and polarity in a wide variety of organs.[67,68]

Nidogens. Two nidogens, nidogen 1 and 2, also known as *entactin 1* and *2*, are distinct gene products. Both are relatively small molecules (see Fig. 51-4D), which bind laminins at a specific site within the γ1 and the γ3 chain,[71] but also collagen IV, perlecan, and fibulins. It has been proposed that nidogens act as connecting elements between the collagen IV and laminin networks and integrate other basement membrane components into this specialized extracellular matrix.[47,48] Targeted ablation of nidogens in mice showed that the loss of either isoform has no effect on basement membrane formation and organ development, but lack of both results in severe defects of the lung and the heart[72] that are not compatible with life. Interestingly, despite the ubiquitous presence of nidogens in basement membranes, aberrations did not occur in all basement membranes, suggesting distinct roles for nidogens in different basement membranes.[72]

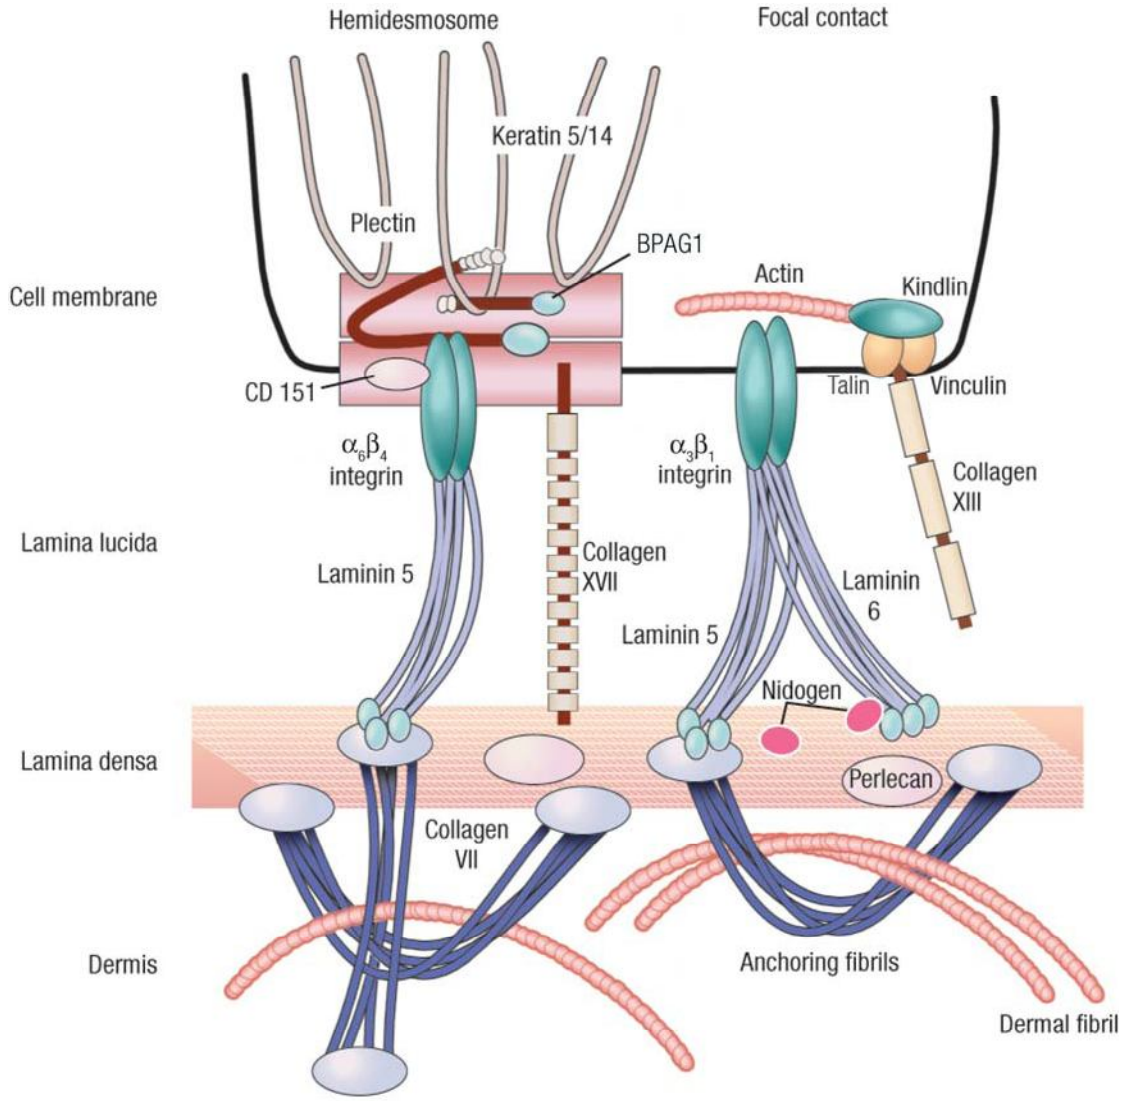
Heparan Sulfate Proteoglycans. Another class of ubiquitous integral basement membrane constituents are the proteoglycans.[73] Three proteoglycans are characteristically present in vascular and epithelial basement membranes: perlecan, agrin, and bamacan. They consist of a core protein of various lengths, and the first two carry primarily heparan sulfate side chains, whereas the latter carries primarily chondroitin sulfate. The name *perlecan* is derived from its rotary shadowing appearance reminiscent of a string of pearls. Perlecan represents a complex multidomain proteoglycan with enormous dimensions and a number of post-translational modifications.[74] Knockout mice lacking perlecan exhibited abnormalities in many tissues, including basement membranes, and embryonic lethality. The basement membranes deteriorated in regions under increased mechanical stress, such as myocardium or skin, resulting in lethal cardiac abnormalities and skin blistering.[73,74] Agrin is a major heparan sulfate proteoglycan of neuromuscular junctions and renal tubular basement membranes. Bamacan is likely to be the chondroitin sulphate proteoglycan previously identified in many basement membranes. The proteoglycans are capable of interactions with several other basement membrane components and are believed to contribute to the overall architecture of the basement membrane as well as provide tissue-specific functions. The high sulfate content of the proteoglycans makes them highly negatively charged and hydrophilic, and the charge density is responsible for providing the selective permeability of the glomerular basement membrane.

Syndecans are transmembrane heparan sulfate proteoglycans present on most cell types, including basal keratinocytes of the epidermis. The extracellular domains have affinity for laminins and, presumably through these interactions, they regulate a variety of biologic processes, ranging from growth factor signaling, cell adhesion, and cytoskeletal organization, to infection of cells with microorganisms.[75]

Fibulins. Fibulins are a family of six highly conserved, calcium-binding extracellular matrix proteins. They are located in vessel walls, basement membranes, and microfibrillar structures and they have overlapping binding sites for a variety of ligands, both basement membrane proteins and components of the interstitial connective tissues.[76] Therefore, fibulins are believed to function as intermolecular bridges that stabilize the supramolecular organization of extracellular membrane structures, such as elastic fibers and basement membranes. Genetic defects of the genes encoding fibulin 4 and 5 cause different forms of cutis laxa.[77]

EPITHELIAL-SPECIFIC BASEMENT MEMBRANE COMPONENTS

The dermal-epidermal junction of skin is an excellent example of specific divergence in basement membrane structure. The structural components of hemidesmosomes, anchoring filaments, and anchoring fibrils in the basement mem-



▲ **FIGURE 51-7** Model of the hypothetical relationships of molecules within the dermal-epidermal junction basement membrane. The illustration depicts laminin 332 as the bridge between the transmembrane hemidesmosomal integrin $\alpha_6\beta_4$ and the collagen VII NC-1 domain. The tight binding of laminin 332 to $\alpha_6\beta_4$ and to collagen VII provides the primary resistance to frictional forces. The transmembrane collagen XVII also participates in this stabilization, because its extracellular domain also binds laminin 332. Within the epithelial cell, the transmembrane elements bind the proteins of the hemidesmosomal dense plaque, bullous pemphigoid antigen (BPAG)1 and plectin, which then associate with the keratins. Collagen XVII binds BPAG1, integrin $\alpha_6\beta_4$, and plectin, and integrin $\alpha_6\beta_4$ binds plectin. The laminin 5-6 complex is shown within the basement membrane between hemidesmosomes, bound by integrin $\alpha_3\beta_1$, and associated with the intracellular proteins kindlin, talin, and vinculin. This complex presumably maintains basement membrane stability. In vitro, integrin $\alpha_3\beta_1$, kindlin, talin, and vinculin, and another transmembrane collagen, type XIII, are localized to the focal contacts, which may function as the link between the basement membrane and the epithelial cortical actin network. In the lamina densa, collagen IV and perlecan networks are stabilized by nidogen. Anchoring fibrils are secured to the lamina densa by the NC-1 domain of collagen VII. The fibrils project into the dermis and either terminate in anchoring plaques or loop back to the lamina densa. The anchoring fibril network entraps dermal fibrils, thus securing the adhesion of the lamina densa to the papillary dermis. None of the molecules is drawn to scale.

brane zone are quite well characterized (for review, see refs. 47–51, 78, 79). A cartoon depicting the relative locations of the proteins found at the dermal-epidermal junction is shown in Figure 51-7. These proteins are listed in Table 51-3 and discussed in the following sections.

Hemidesmosomes

Ultrastructurally, the hemidesmosome closely resembles one-half of the desmosome at cell-cell junctions in the epidermis. However, the components of these two structures are distinct. Characterization of the hemidesmosomal proteins was initially aided by the use of autoantibodies in serum of patients with bullous pemphigoid (Fig. 51-8), which recognized antigens with a mass from 120 kd to 230 kd.[27,80,81] Cloning of the cDNAs for the molecules helped identify three distinct polypeptide chains: 230 kd, 180 kd, and 120 kd. The 230-kd protein, *BPAG1* (bullous pemphigoid antigen 1, or BP230), is a coiled-coil dimeric protein with homology to plakins, which bind intermediate filaments.[80,82] BPAG1 is the major component of the hemidesmosomal inner dense plaque. In a transgenic mouse model, deletions in BPAG1 caused epidermolysis bullosa simplex[78] but no human mutations have been found so far.[83] The 180-kd protein, previously called *BPAG2* or *BP180*, and the major

TABLE 51-3
Hemidesmosomal and Basement Membrane Zone (BMZ) Targets in Skin Disease

	Hemidesmosome/BMZ Component	Autoimmune Target	Genetic Target

Anchoring fibril proteins	Collagen VII	EBA	DEB

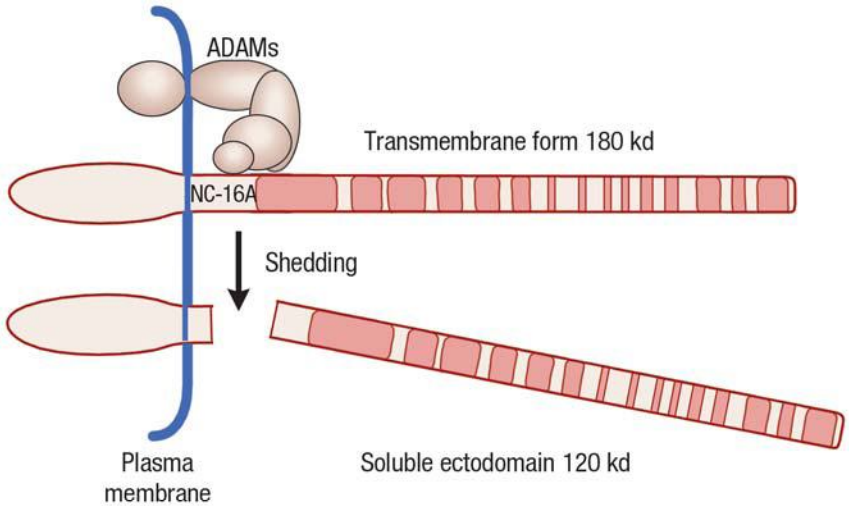
BP = bullous pemphigoid (see Chap. 54); CP = cicatricial pemphigoid (see Chap. 55); DEB = dystrophic EB (see Chap. 60 for all); EB = epidermolysis bullosa; EBA = EB acquisita (see Chap. 58); EBS = EB simplex; EBS-MD = EBS with muscular dystrophy; JEB= junctional EB; JEB-PA = JEB with pyloric atresia; KS = Kindler syndrome; LAD = linear immunoglobulin A dermatosis (see Chap. 56); PG = pemphigoid gestationis (see Chap. 57).

antigen in bullous pemphigoid, is a transmembrane collagen now known as *collagen XVII*, where the collagenous domain is extracellular.[84–87] In fact, collagen XVII is a prototype of the novel protein family of collagenous transmembrane proteins, type II transmembrane molecules with one or more collagenous stretches in the extracellular domain.[88] Mutations in collagen XVII cause junctional epidermolysis bullosa (see Chap. 60), indicating that it stabilizes interactions of basal keratinocytes with the basement membrane. Its intracellular ligands are plectin, BPAg-1 and β_4 integrin, and the extracellular ligands α_6 integrin and laminin 332.[78,79] The 120-kd protein is the ectodomain of collagen XVII,[85,87,88] which is shed from the cell surface by proteinases of the ADAM (A disintegrin-like and metalloproteinase-containing) family[89] through cleavage within the juxtamembranous NC-16 domain (Fig. 51-9). Plectin, another dimeric plakin homologue, is also a component of the hemidesmosome.[78] However, its tissue distribution is not limited to hemidesmosome-containing basement membranes. Mutations of plectin result in epidermolysis bullosa simplex and progressive muscular dystrophy and, in some cases, junctional epidermolysis bullosa with pyloric atresia (see Chap. 60), indicating a role for plectin in the stability of cell-basement membrane adhesion in a variety of tissues.

One key component of the hemidesmosome is the integrin $\alpha_6\beta_4$.[78] It has a high affinity for laminin 332, and therefore is essential to integration of the hemidesmosome with the underlying basement membrane and stroma.[78,79] Mutations in either the α6 or β4 chains result in dermal-epidermal instability. In mice, null mutations cause severe junctional epidermolysis bullosa.[78] In humans, different mutations in the α6 or β4 chains are associated with variably severe skin blistering associated with pyloric atresia.[79,83]

A member of the widely expressed cell surface transmembrane proteins of the tetraspanin family, CD151, is also a component of the hemidesmosome. It forms complexes with $\alpha_3\beta_1$ and $\alpha_6\beta_4$ integrins at the basolateral surface of basal keratinocytes and stabilizes their functions by pro-

▲ **FIGURE 51-8** **A.** Skin blisters in bullous pemphigoid result from antibody-mediated loss of function of the adhesion molecule collagen XVII. **B.** Indirect immunofluorescence staining of human skin with a pemphigoid serum that contains autoantibodies to collagen XVII.



▲ **FIGURE 51-9** Schematic representation of collagen XVII and its ectodomain shedding. Collagen XVII is a hemidesmosomal transmembrane protein with an intracellular N-terminus. The extracellular C-terminus (ectodomain) contains several collagenous subdomains (*brown*) and intervening non-collagenous sequences (*beige*). The ectodomain can be shed from the cell surface by proteinases of the ADAMs (A disintegrin-like and metalloproteinase-containing) family, themselves transmembrane proteins. Thus, the 180-kd full-length molecule yields a shorter soluble ectodomain of 120 kd. The 180-kd full-length molecule is the classic bullous pemphigoid antigen-2, and the ectodomain is the 120-kd linear immunoglobulin A (IgA) dermatosis antigen. Further degradation of the C-terminus of the ectodomain results in the 97-kd linear IgA dermatosis antigen.

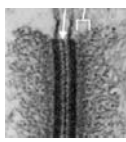
viding a framework for the spatial organization of the different components.[90] Dissociation of the CD151-integrin complexes permits remodeling of epithelial cell interactions with the basement membrane and cell migration.[91,92] CD151-null mice have apparently normal tissue morphology, including hemidesmosomes, but exhibit some functional aberrations, e.g., poor keratinocyte migration in explant cultures.[93] A rare human genetic condition delivered indirect information on the functions of CD151. In addition to the expression of CD151 in several tissues like the kidney and the skin, its gene also encodes the MER2 blood group antigen on erythrocytes. Homozygous CD151-null mutations were identified in three MER2-negative patients, who also presented with hereditary nephritis, sensorineural deafness, pretibial epidermolysis bullosa, and β-thalassemia minor.[94] These symptoms suggest that CD151 is important for the assembly of the basement membrane in the kidney, skin, and inner ear and plays a role in erythropoiesis.

Other Epidermal Adhesion Complexes

In addition to the hemidesmosomal components, other adhesion molecules are known to be present at the basolateral aspect of basal keratinocytes, for example integrin $\alpha_3\beta_1$, the receptor for the laminin 332–311 complex in the basement membrane between the hemidesmosomes,[95] and another transmembrane collagen, type XIII.[96] Since these proteins are localized to focal contacts in vitro, together with vinculin and talin, they are predicted to function as the link between the basement membrane and the epithelial cortical actin network. Recently, a novel intracellular component of this complex, kindlin-1, was identified by the genetic studies. The kindlin-1 gene, KIND1, is mutated in the Kindler syndrome,[97–99] a disorder with skin blistering in infancy, progressive poikiloderma, skin atrophy, pigment anomalies, and, occasionally, skin cancer. In the epidermis, kindlin-1 is expressed at the basolateral surface of basal keratinocytes, and in cultivated epithelial cells it co-localizes with vinculin, a marker of integrin-mediated cell-matrix adhesions, and actin microfilaments.[97,100] These observations suggest that kindlin-1 is necessary for the stability of the dermal-epidermal junction and that, in addition to hemidesmosomes, tethering the actin cytoskeleton to cell-matrix adhesions offers alternative means to anchor basal epithelial cells to the basement membrane.[79]

Anchoring Filaments

The anchoring filaments contain laminin 332 and the ectodomain of collagen XVII,[67,68,79] two ligands that interact with each other through noncovalent bonds.[101] The ectodomain of collagen XVII, which protrudes from the plasma membrane into the lamina lucida, has a loop structure consistent with its role as an anchoring filament protein.[102] The molecular characteristics of this collagen are delineated in Hemidesmosomes.[84–88] Laminin 332 is a disulfide-bonded complex of α3, β3, and γ2 chains. The two splice variants of the α3 chain, α3A and α3B, associate with the α3 and γ2 chains to form laminin 3A32 and 3B32 (see Fig. 51-6), previously known as *laminin-5*.[68] Rotary shadowing imaging indicates that laminin 332 has a rod-like structure terminating in the globular regions (see Fig. 51-4F), a shape consistent with its role as an anchoring filament protein. The individual chains are considerably truncated relative to other laminin chains, and this truncation is reflected in the loss of the structures equivalent to the short arms of other laminins. Additionally, the α3 and γ2 chains are proteolytically processed after secretion from the keratinocyte, further trimming the short arms.[103,104] The C-terminus of the α chain, longer than that of the β and γ chains, comprises five globular LG modules, LG1 through LG5, which interact with cell surface receptors. The $\alpha_3\beta_1$ and $\alpha_6\beta_4$ integrins have affinity for the LG1-3 domains,[105] whereas the LG4-5 tandem has affinity for syndecans and β-dystroglycan on the keratinocyte surface.[106] The LG4-5 modules are proteolytically cleaved in most laminins, a process which may modulate interactions with cell surface receptors.[67,68] Laminin 332 forms covalent complexes with laminin 311 (α3β1γ1), binds to the NC-1 domain of collagen VII, the anchoring fibril protein[79] and to the distal ectodomain of collagen XVII.[101] Genetic evidence demonstrates that laminin 332 is essential in keratinocyte adhesion, as null mutations in any of its component α3, β3, or γ2 chains result in severe Herlitz junctional epidermolysis bullosa (see Chap. 60).[83] Targeted disruption of the mouse lama3 gene prevented the synthesis of both laminin 332 and 311 molecules and resulted in abnormal hemidesmosomes, lack of survival of mutant epithelial cells, severe junctional blistering, abnormalities of ameloblast differentiation in developing teeth, and perinatal lethality.[107] Therefore, the severity of the laminin 332 null phenotype reflects the loss of its ability to bridge the hemidesmosomes and the anchor-



ing fibrils, resulting in a separation within the lamina lucida.

Epithelial Lamina Densa

The basement membrane beneath and between the hemidesmosomes contains the α1-α2–containing collagen IV network, probably some α1-α2-α5-α6–containing collagen IV network, as well as nidogen, perlecan, and laminin α3 and α5-containing molecules.[47–49,61] The N-terminus of the α3 chain lacks the so-called *LN modules*, which allow self-polymerization of other laminin isoforms. However, the α3 chain can associate with the β1 and γ1 chains of laminin 311, previously laminin-6, which has the unique property of forming disulfide-bonded dimers with laminin 332.[67,68] It is probable that the major α3-containing laminin in the lamina densa between hemidesmosomes is the laminin 332-311 complex.[67,68,79] As the laminin α3 chain is a ligand for integrin $\alpha_3\beta_1$ present between hemidesmosomes, binding of laminin 332-311 complex to the intracellular actin cytoskeleton is likely to be mediated by integrin $\alpha_3\beta_1$. This is consistent with studies in mice in which targeted ablation of the integrin α_3 chain causes loss of the basement membrane between hemidesmosomes but not beneath them.[108] The N-termini of laminin 332 bind to collagen VII, a component of the anchoring fibrils located in the sub-lamina densa, so that anchoring filaments and fibrils are directly connected.[109] The laminin 332-311 complex and laminin 511 (α5β1γ1), previously laminin-10, contain a γ1 chain and can therefore bind nidogen 1 and 2 and the collagen IV network.[70,71] Further, nidogen 1 and fibulin 1 and 2 were shown to be ligands for recombinant N-terminal γ2 chain of laminin 332.[110] These interactions are important for the integration of laminin 332 into the extracellular matrix before the maturation of the γ2 chain,[103] as a substantial portion of N-terminus of the γ2 chain is cleaved in human adult skin.[79] Yet another link, which strengthens dermal-epidermal cohesion, is provided by molecular interactions between perlecan within the lamina densa and fibrillin 1 in the microfibrils.[111]

Anchoring Fibrils

Collagen VII is the major component of the anchoring fibrils.[55,57,112] The collagen VII molecule is distinguished from other collagens in that it has a very long triple-helical domain, 450 nm in length. Globular domains exist at both ends of the triple helix, and the N-terminal domain NC-1 is very large and trident-like (see Fig. 51-4E). The smaller C-propeptide, NC-2, is believed to facilitate the formation of the antiparallel, centrosymmetric dimers,[113] before it is removed by the metalloproteinase bone morphogenetic protein 1[114] to yield a mature collagen VII. The dimers are covalently cross-linked through disulfide bonds at the carboxy terminus, and they aggregate laterally to form the anchoring fibrils.[112] The fibrils are further stabilized by tissue transglutaminase, which catalyzes the formation of covalent γ-glutamyl-ε-lysine cross-links.[115]

The NC-1 domain of collagen VII binds to laminin-5 and collagen IV within the lamina densa (see Fig. 51-3A).[116] The triple helical domains of an antiparallel collagen VII dimer make the length of the anchoring fibril. It extends perpendicularly from the lamina densa and either loops back into the lamina densa or inserts into the anchoring plaques.[55–57] The anchoring plaques are electron-dense structures that contain collagen IV and laminin 332, and perhaps other basement membrane components, but which are believed to be independent of the lamina densa itself.[55] They are distributed randomly in the papillary dermis below the lamina densa and are interrelated by additional anchoring fibrils. The anchoring fibril network forms a scaffold that entraps large numbers of dermal fibrils, securing the lamina densa to the subjacent dermis.[55–57,112] In the acquired form of epidermolysis bullosa, epidermolysis bullosa acquisita (see Chap. 58), and in bullous systemic lupus erythematosus (see Chap. 156), autoantibodies target mainly the NC-1 domain of collagen VII.[117,118]

Mutations in *COL7A1*, the gene encoding collagen VII, result in dystrophic epidermolysis bullosa (see Chap. 60). As of 2006, more than 300 *COL7A1* mutations have been found in both recessive and dominant forms of dystrophic epidermolysis bullosa (Fig. 51-10), and the spectrum of biologic and clinical phenotypes is much broader than anticipated.[79,83,119] In two different mouse models, complete or partial deficiency of collagen VII recapitulated the clinical and morphologic characteristics of recessive dystrophic epidermolysis bullosa in humans.[120,121] These mice will be useful for testing of molecular therapy strategies for dystrophic epidermolysis bullosa. A number of such therapies, ranging from protein[122] therapy to transposon-mediated gene transfer,[123] have been considered. Gene augmentation in an ex vivo approach currently seems to be most promising as a first step, in particular for recessive dystrophic epidermolysis bullosa.[124–127] This strategy comprises genetic correction of patient keratinocytes in vitro,

▲ **FIGURE 51-10** Skin fragility and blistering in dystrophic epidermolysis bullosa. Functional deficiency of collagen VII as a result of mutations in the *COL7A1* gene leads to trauma-induced separation of the epidermis and the dermis. The blister roof is below the lamina densa, leading to scar formation on healing of the blisters.

and their cultivation into epithelial sheets for grafting onto the patient's skin. Results with a canine dystrophic epidermolysis bullosa model seem promising: transduction of epidermal cells with a retroviral vector containing the entire collagen VII cDNA enhanced expression and deposition of collagen VII at the dermal-epidermal junction.[126] In another approach, nonviral gene transfer using cotransfection of C31 integrase and human collagen VII resulted in the expression of the protein in collagen VII–deficient DEB keratinocytes.[124] As fibroblasts also contribute to the synthesis of collagen VII, their suitability for gene therapy approaches is under investigation.[128,129]

Cellular Origin of the Dermal-Epidermal Basement Membrane

The basement membrane constituents are products of both epithelial and mesenchymal cells. In vitro modeling of basement membrane formation clearly shows that, under at least some conditions, the dermal-epidermal junction basement membrane is contributed to by both tissue compartments, and it has been proposed that differentiated fibroblasts exist adjacent to epithelial tissues in vivo, which produce basement membrane components and assist in basement membrane assembly.[130,131] Of the known basement membrane components, only laminins 332 (laminin-5) and 311A (laminin-6) are exclusively produced by the epidermis. Epithelial cells also manufacture most of collagen VII, whereas mainly mesenchymal cells synthesize collagen IV, nidogen, perlecan, and the laminin α2 chain.[131] Because the mesenchymal products are translocated to the basolateral epithelial surface where they condense, that surface must provide the localization cues. Integrins $\alpha_6\beta_4$ and $\alpha_3\beta_1$ and collagen XVII have been implicated in this process, suggesting that the laminins coordinate basement membrane polymerization.[67,68,101] As nidogen is required for stabilization of the basement membrane, and because it is a mesenchymal product, it is likely that the dermis is essential to development of basement membranes.[133] Studies using different skin equivalent culture models have demonstrated that a tight interplay between fibroblasts and keratinocytes, in terms of both their matrix production and secretion of soluble signals, regulates the formation of the dermal-epidermal basement membrane.[132,134] An interesting regulatory step may be added by dermal enzymes (e.g., bone morphologic protein 1), which process epithelial cell products, such as laminin 332 and procollagen VII, to mature basement membrane molecules.[103,104,114]

CHAPTER 52

Pemphigus

John R. Stanley

The term *pemphigus* refers to a group of autoimmune blistering diseases of skin and mucous membranes that are characterized histologically by intraepidermal blisters due to acantholysis (i.e., separation of epidermal cells from each other) and immunopathologically by in vivo bound and circulating immunoglobulin G (IgG) directed against the cell surface of keratinocytes.[1] The nosology of this group of diseases is outlined in Table 52-1. Essentially, pemphigus can be divided into four major types: vulgaris, foliaceus, paraneoplastic (see Chap. 53), and IgA pemphigus (see Chap. 34). In pemphigus vulgaris (PV), the blister occurs in the deeper part of the epidermis, just above the basal layer, and in pemphigus foliaceus (PF), also called *superficial pemphigus*, the blister is in the granular layer.[2]

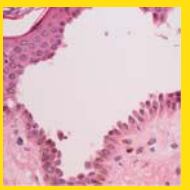
The history of the discovery of pemphigus, and its various forms, is covered in Lever's classic monograph *Pemphigus and Pemphigoid*.[2] Both PV and PF display a spectrum of disease. Various points along these spectra have been given unique names, but because the presentation of these diseases is fluid, patients' disease usually crosses these artificial designations over time. Thus, patients with PV may present with more localized disease, one form of which is called *pemphigus vegetans of Hallopeau*. This may become slightly more extensive and may merge into pemphigus vegetans of Neumann. Finally, with more severe disease, full-blown PV may appear. Similarly, patients with PF may present with more localized disease, represented by pemphigus erythematosus. However, these patients often go on to more widespread PF.

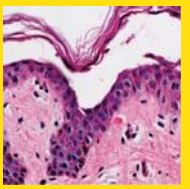
TABLE 52-1
Classification of Pemphigus

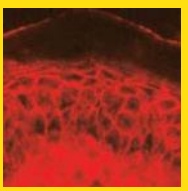
TYPE	FORM
Pemphigus vulgaris	Pemphigus vegetans: Localized Drug-induced
Pemphigus foliaceus	Pemphigus erythematosus: Localized Fogo selvagem: Endemic Drug-induced
Paraneoplastic pemphigus	
IgA pemphigus	Sub-corneal pustular dermatosis Intraepidermal neutrophilic IgA dermatosis

IgA = immunoglobulin A.

PEMPHIGUS AT A GLANCE







- Two major types: Vulgaris and foliaceus.
  - Pemphigus vulgaris: Erosions on mucous membranes and skin; flaccid blisters on skin
  - Pemphigus foliaceus: Crusted, scaly skin lesions
- Pathology.
  - Pemphigus vulgaris: Suprabasilar acantholysis
  - Pemphigus foliaceus: Sub-corneal acantholysis
- Direct immunofluorescence shows immunoglobulin G (IgG) on the keratinocyte cell surface of the patient's skin; indirect immunofluorescence shows IgG in patient's serum that binds the cell surface of normal keratinocytes.
- Autoantigens are desmogleins, transmembrane desmosomal adhesion molecules.
- Therapy includes topical and systemic corticosteroids and immunosuppressives.

The discovery by Beutner and Jordon in 1964 of circulating antibodies against the cell surface of keratinocytes in the sera of patients with PV pioneered our understanding that PV is a tissue-specific autoimmune disease of skin and mucosa. Ultimately, their work led the way to the discoveries of autoantibodies in other autoimmune bullous diseases of the skin.[3]

EPIDEMIOLOGY

Several retrospective surveys of patients with PV, PF, or both clearly indicate that the epidemiology of pemphigus is dependent on both the area in the world that is studied as well as the ethnic population in that area.[2,4–12] The prevalence of pemphigus of both types in men and women is nearly equal in most areas; however, notable exceptions are the predominance of women in an endemic focus of PF in Tunisia, and a predominance of men in an endemic focus of PF in Colombia.[8,13] The mean age of onset of disease is approximately 40 to 60 years of age; however, the range is broad, and disease may start in the elderly and in children.

Incidence and Prevalence

PEMPHIGUS VULGARIS PV is more common in Jews and probably in people of Mediterranean descent and from the Middle East. This same ethnic predominance does not exist for PF. Therefore, in areas where the Jewish, Middle Eastern, and Mediterranean population predominates, the ratio of PV to PF cases tends to be higher. For example, in New York, Los Angeles, and Croatia, the ratio of PV to PF cases is approximately 5:1; in Iran the ratio is 12:1; whereas in Finland, it is only 0.5:1.0, and in Singapore it is 2:1. Similarly, the incidence of pemphigus is variable depending on location: In Jerusalem, the incidence of PV has been estimated to be 1.6 per 100,000 population per year and in Iran approximately 10.0 per 100,000 per year; in Finland, the incidence is much lower, 0.76 per million population. In France and Germany, the incidence of PV is approximately 1.0 case per million population per year and that of PF is 0.5 cases per million per year. The prevalence and incidence of PF are also very dependent on its location, as best exemplified by fogo selvagem and other forms of endemic PF in Colombia and Tunisia.

FOGO SELVAGEM The first recognition of endemic PF was in Brazil and is called *fogo selvagem*, which means "wild fire" in Portuguese. It is a disease that is clinically, histologically, and immunopathologically the same as sporadic PF in any individual patient, but its epidemiology is unique.[14,15] Fogo selvagem is endemic in the rural areas of Brazil, especially along inland riverbeds. The geographic distribution of disease clustering is similar to that of a black fly, *Simulium nigrimanum*, thought by natives to be a vector of this disease. A study of potential environmental risk factors has also implicated the bite of this black fly, showing it to be significantly more frequent among those with the disease compared to an age-, sex-, and occupation-matched control population with unrelated dermatoses.[16] The prevalence on some well-studied Indian reservations in rural Brazil can be as high as 3.4 percent, with the incidence up to 0.8 to 4.0 new cases per 1000 people per year.[15,17] On the reservation in Limao Verde, up to 55 percent of unaffected individuals have a low-level IgG1 antibody response against desmoglein 1, the PF autoantigen (see Pemphigus Antigens), which becomes an IgG4 response of higher titer against a more pathogenic epitope in disease.[15] These results suggest that some environmental agent (e.g., insects or other infectious disease agent) may trigger a low-level autoantibody response that becomes more generalized by intramolecular epitope spreading in genetically susceptible individuals. With this theory in mind, it is interesting that 40 percent to 80 percent of patients from Brazil with the insect-borne diseases onchocerciasis, leishmania, and Chagas disease have low-level anti-desmoglein 1 antibodies, but patients with other infectious diseases from Brazil rarely have such antibodies.[18]

Fogo selvagem occurs often in children and young adults, unlike sporadic PF, which is a disease of mostly middle-aged and older patients (although rare cases in children have been reported[19]). Also unlike PF, fogo selvagem occurs not infrequently in genetically related family members, although it is not contagious. This fact probably implies a common exposure, as well as susceptibility. There is no known racial or ethnic predominance, and anyone moving into an endemic area may be susceptible to disease. Finally, the development of the rural endemic areas of Brazil decreased the incidence of disease. Certainly, this fascinating disease holds clues to understanding how this autoimmune response is triggered.

ETIOLOGY AND PATHOGENESIS

Electron Microscopy

Ultrastructural studies of the blisters in pemphigus have focused on the appearance of desmosomes, because these are the most prominent cell-to-cell adhesion junctions in stratified squamous epithelia. Early studies of PV lesions seemed to demonstrate early dissolution of cell-to-cell membrane contacts between intact desmosome junctions, with later separation and disappearance of the desmo-

somes.[20] In acantholytic cells, separation of the opposing desmosomal plaques was seen, leaving half-desmosomes with the tonofilaments still inserted into the plaque. Such observations of acantholysis with half-desmosomes without tonofilament collapse have also been reported in a mouse model of PV.[21,22] In contrast, the addition of PV serum to cultured keratinocytes affects desmosome structure by causing the retraction of the tonofilaments that normally attach to desmosomal plaques.[23] Biopsies of uninvolved skin from patients with PV show disruption of desmosomes and decreased numbers of desmosomes.[24] All these data confirm that at various time points during acantholysis, the desmosome is affected and ultimately destroyed, consistent with the cell biologic data discussed in Pathophysiology of Acantholysis.

Similarly, in lesions of PF, electron microscopy was reported to show abnormalities in desmosome structure in early acantholysis and in the mucosa, which binds autoantibodies but does not undergo gross acantholysis.[25,26] The earliest of these changes may be retraction of tonofilaments from the desmosome-dense plaque. Later, there may be a decrease or absence of desmosomes. These electron microscopic studies are difficult to interpret regarding the time course of events, but they all indicate that, at least in some stage of acantholysis, desmosomes are destroyed.

Immunopathology

IMMUNOFLUORESCENCE The hallmark of pemphigus is the finding of IgG autoantibodies against the cell surface of keratinocytes. These autoantibodies were first discovered in patients' sera by indirect immunofluorescence and soon thereafter were discovered by direct immunofluorescence of patients' skin.[27] Essentially all patients with active PV or PF have a positive finding on a direct immunofluorescence test for IgG on the cell surface of keratinocytes in perilesional skin (Fig. 52-1A).[28] The diagnosis of pemphigus should be seriously questioned if the test result of direct immunofluorescence is negative. Depending on the substrate used for indirect immunofluorescence, more than 80 percent of patients with pemphigus have circulating antiepithelial cell surface IgG (Fig. 52-1B).[29] Patients with early localized disease and those in remission are most likely to have negative findings on an indirect immunofluorescence test.

Patients with PV and those with PF usually display similar direct and indirect immunofluorescence findings with IgG on the cell surface of epidermal cells throughout the epidermis. Therefore, it is usually not possible to differentiate the two diseases by the pattern of immunofluorescence. The substrate used to detect pemphigus antibody binding in indirect immunofluorescence greatly influences the sensitivity of the test, however. In general, monkey esophagus is more sensitive for detecting PV antibodies and guinea pig esophagus is a superior substrate for detecting PF antibodies.[29]

There is a positive, but imperfect, correlation between the titer of circulating anti–cell surface antibody and the disease activity in PV and in PF.[30] Although this correlation may hold in general, and although patients in remission often show serologic remission with negative direct and indirect immunofluorescence findings,[31,32] disease activity in individual patients does not necessarily correlate with antibody titer. Therefore, in the day-to-day management of these patients, following disease activity is much more important than following antibody titer.

Pemphigus erythematosus is a localized form of PF with a characteristic direct immunofluorescence finding of immunoreactants, usually IgG and C3, at the basement membrane zone of erythematous facial skin. These immunoreactants are in addition to the epidermal cell surface IgG.[33]

PEMPHIGUS ANTIGENS Immunologic evidence and molecular cloning have demonstrated that pemphigus antigens are desmogleins, transmembrane glycoproteins of desmosomes (cell-to-cell adhesion structures).[34,35] Immunoelectron microscopy has localized both PV and PF antigens to the cell surface of keratinocytes in desmosomal junctions.[36–38]

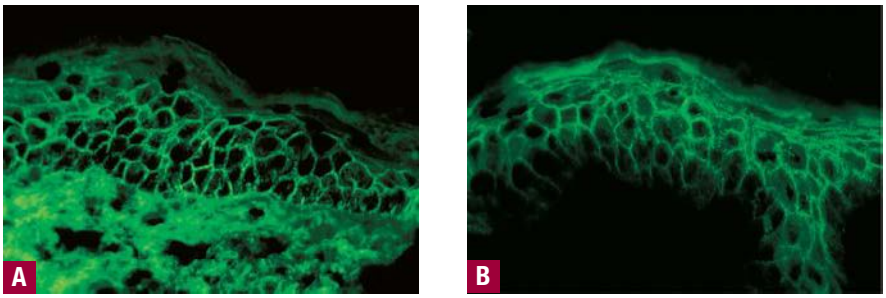
Characterization of pemphigus antigens at a molecular level has confirmed that they are molecules in desmosomes. Immunoprecipitation and immunoblotting studies with extracts from cultured keratinocytes or epidermis have demonstrated that PF antigen (as well as the fogo selvagem antigen) is desmoglein 1, a 160-kd transmembrane glycoprotein of desmosomes.[39–41]

Molecular cloning of the complementary DNA that encodes PV antigen identified it as desmoglein 3, another desmoglein isoform encoded by a separate gene.[42] All patients with PV have anti–desmoglein 3 antibodies, and some of these patients also have anti–desmoglein 1 antibodies.[43,44] Patients with PV that affects predominantly mucous membranes tend to have only anti–desmoglein 3 antibodies, whereas those with mucocutaneous disease usually have both anti–desmoglein 3 and anti–desmoglein 1 antibodies.[45–47] The dual antibody status of some patients with PV is in contrast to the single antibody status of PF patients, who have antibodies against only desmoglein 1.

Desmogleins 1 and 3 are closely related members of the cadherin supergene family. The original members of this family (e.g., E-cadherin) have been shown to be transmembrane, calcium-dependent, homophilic cell adhesion molecules. Presumably, the desmogleins fulfill similar functions in desmosomes. PF and PV sera bind calcium-sensitive, conformational epitopes on desmogleins 1 and 3, respectively, suggesting that they might interfere with a calcium-sensitive adhesion function.[48,49]

Although other cell surface molecules, such as acetylcholine receptors, may modulate adhesion, their direct involvement in the pathophysiology of pemphigus is controversial.[50–52]

ENZYME-LINKED IMMUNOSORBENT ASSAY FOR IMMUNODIAGNOSIS For diagnosis of disease, antigen-specific enzyme-linked



▲ **FIGURE 52-1** Immunofluorescence in pemphigus. **A.** Direct immunofluorescence for immunoglobulin G (IgG) of perilesional skin from a patient with pemphigus vulgaris. Note cell surface staining throughout the epidermis. **B.** Indirect immunofluorescence with the serum from a patient with pemphigus foliaceus on normal human skin. Note IgG on the cell surface throughout the epidermis.

immunosorbent assays have been shown to be more sensitive and specific (e.g., they can differentiate PV from PF) than immunofluorescence, and their titer correlates better than that of indirect immunofluorescence with disease activity.[43,53] These assays use desmogleins 1 and 3 bound to plates, which are then incubated with patient sera and developed with anti-human IgG reagents. Such assays can differentiate between PV and foliaceus.[43,49,53,54] In most cases, enzyme-linked immunosorbent assay is positive for desmoglein 3 (but not desmoglein 1) in mucosal PV, is positive for both desmogleins 3 and 1 in PV with both mucosal and significant skin involvement, and is positive for only desmoglein 1 in PF.

Pathophysiology of Acantholysis (See Chap. 51)

Pemphigus autoantibodies both from patients with PV and from those with PF are pathogenic. The occurrence of neonatal PV demonstrates that maternal IgG can cross the placenta and cause disease.[55] However, neonatal PF is very rare.[56]

Essentially, neonatal PV results from the passive transfer of IgG to the fetus. Similar experimental passive transfer studies show that PV and PF IgG cause acantholysis at the suprabasilar and granular layers of the epidermis, respectively, when added to skin in organ culture.[57,58] Antibody-induced acantholysis in this system occurs without the participation of complement or inflammatory cells.

Further compelling evidence of autoantibody-mediated pathology in pemphigus comes from studies of the passive transfer of PV and PF IgG to neonatal mice. These mice develop blisters and erosions that clinically and histologically mimic the corresponding type of pemphigus.[59,60] Complement fixation is not necessary to produce disease, and, consistent with this observation, even monovalent Fab′ immunoglobulin fragments are pathogenic in these mice.[60,61]

The pathology-causing autoantibodies in pemphigus are those directed against desmogleins 1 and 3.[35,36] IgG that is affinity purified from PV sera on the extracellular domain of desmoglein 3 can cause suprabasilar acantholysis, the typical histologic finding of PV lesions, when injected into neonatal mice.[62,63] Furthermore, the extracellular domain of desmoglein 3 can adsorb out of PV sera antibodies pathogenic in neonatal mice.[64] Similarly, the extracellular domain of desmoglein 1 can adsorb out all pathogenic antibodies from PF sera, and antibodies affinity purified on desmoglein 1 are pathogenic.[65] Finally, an active animal model of PV has been established by immunizing mice that are not tolerant of desmoglein 3 (i.e., mice whose desmoglein 3 gene has been deleted) to generate an immune response against desmoglein 3.[66] After the passive transfer of lymphocytes from these immunized mice to normal mice, the latter develop clinically and histologically typical lesions of PV and have anti–desmoglein 3 antibodies in their skin and sera.

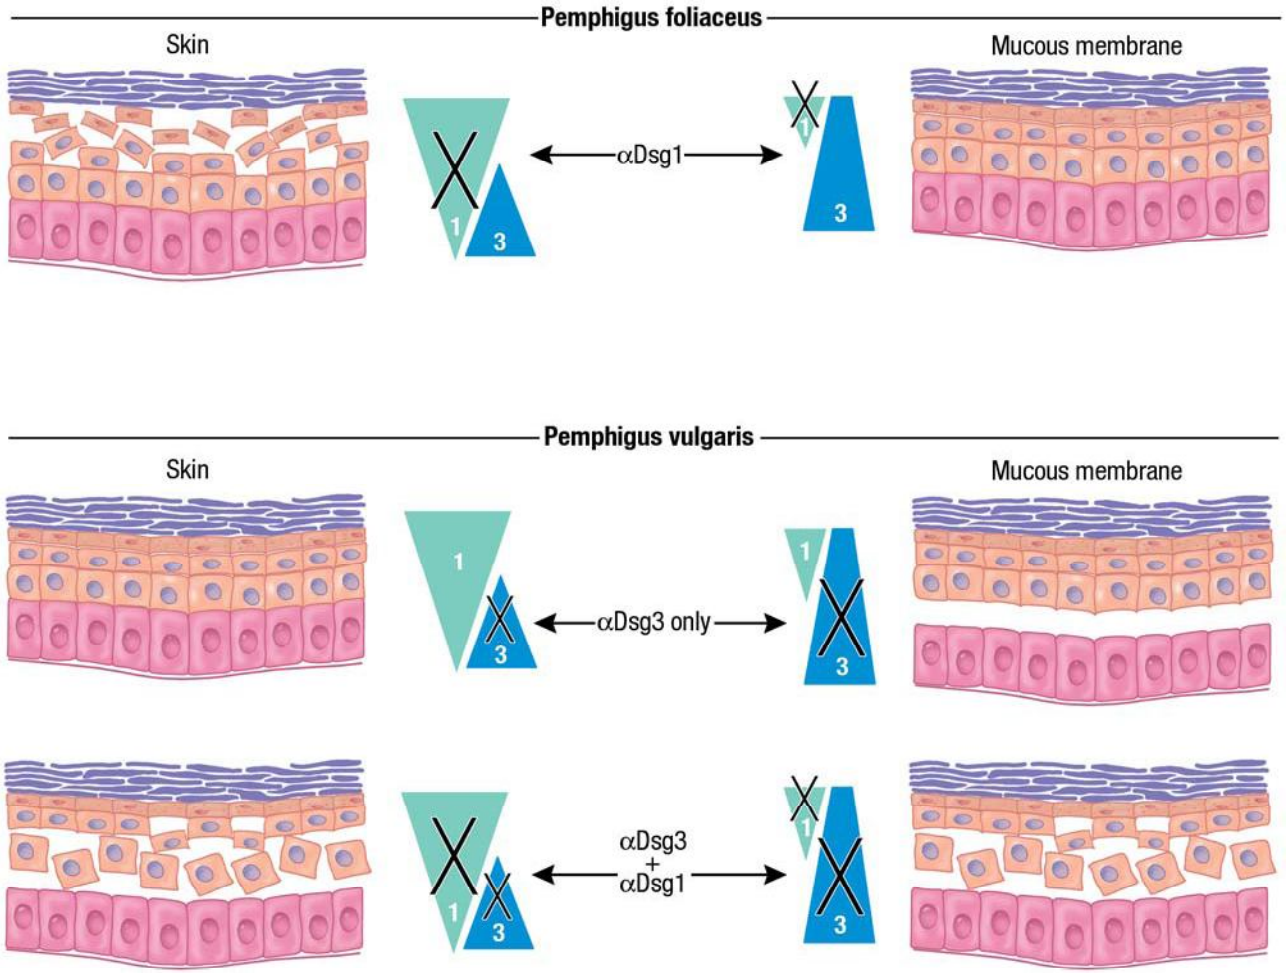
These data strongly suggest that PV and PF autoantibodies against desmogleins 3 and 1, respectively, cause the blister formation in these diseases. They may do so by interfering with a cell-to-cell adhesion function of these desmogleins or with their role in desmosome assembly. If indeed the pathophysiology of pemphigus arises from such antibodies directly inhibiting the function of desmoglein, interfering with the function of the desmoglein in some other way should result in a process that mimics pemphigus. This hypothesis was tested by genetically engineering a mouse with a targeted deletion of the desmoglein 3 gene.[67] The phenotype of this knockout mouse was very similar to that of patients with PV, with suprabasilar blisters developing in the oral mucosa and skin. These data, then, are consistent with the idea that autoantibodies directly cause a loss of adhesion of keratinocytes.

Another line of evidence that inactivation of desmogleins causes the blistering of pemphigus comes from studies of bullous impetigo and staphylococcal scalded-skin syndrome, which are caused by exfoliative toxin released by *Staphylococcus aureus*. Desmoglein 1 is the specific target for exfoliative toxin. The enzyme proteolytically cleaves desmoglein 1, resulting in blisters identical to those seen in PF.[68] Thus, inactivation of desmoglein 1 can cause blisters identical to those seen in PF, which suggests that the anti–desmoglein 1 antibodies in PF patients also inactivate desmoglein 1. Finally, in a mouse model of PV, anti–desmoglein 3 antibodies appear to directly interfere with desmoglein function within the desmosome, causing split desmosomes, without keratin retraction, in areas of acantholysis.[22]

If inactivation of desmoglein isoforms results in blistering, then why do blisters in PV and PF have specific tissue localizations that do not necessarily correlate with the sites at which the antibodies bind by immunofluorescence? In PF, for example, the anti–desmoglein 1 antibodies bind throughout the epidermis and mucous membranes,[69] yet blisters occur only in the superficial epidermis. This apparent paradox has been explained by desmoglein compensation, as outlined in Fig. 52-2. The concept of desmoglein compensation originates in the assumption that autoantibodies against one desmoglein isoform inactivate only that isoform and that another isoform co-expressed in the same area can compensate in adhesion.[70,71] Desmoglein compensation also explains why neonatal PF is so unusual, even though the anti–desmoglein 1 antibodies cross the placenta; in neonatal skin, as opposed to adult skin, desmoglein 3 is co-expressed with desmoglein 1 in the superficial epidermis.[72] The validity of desmoglein compensation has been proven by the demonstration that transgenic mice with forced expression of desmoglein 3 in the superficial epidermis are protected against blistering by passive transfer of PF IgG.[72] Further evidence for desmoglein compensation has been obtained on the genetic level.[73] Specifically, transgenic expression of desmoglein 1 can compensate for genetic loss of desmoglein 3 in knockout mice.

Recently it has been shown that another desmoglein, desmoglein 4, which is in the developing hair cortex and is mutated in some types of autosomal recessive hypotrichosis, is also present in the superficial epidermis, and is a target of some pemphigus antibodies.[74–77] However, the anti-desmoglein 4 antibodies in mucocutaneous PV and in PF also bind desmoglein 1 and do not seem to be sufficient or necessary for acantholysis.[78]

Although the anti-desmoglein antibodies in pemphigus may directly inactivate desmogleins in desmosomes, thereby causing loss of cell adhesion, it is also possible that they deplete the desmosome of desmoglein.[79–82] This effect may occur by depletion of desmoglein from the cell surface before it becomes incorporated into the desmosome, thus decreasing the precursor pool. Another possibility is that pemphigus antibodies might cause depletion of desmoglein directly from the desmosomes. In either case, PV antibodies have been shown to target desmoglein 3 (together with plakoglobin) for endocytosis and lysosomal degradation. It has been shown that adhesion on the cell surface is necessary to prevent endocytosis of organizing desmosomes,[83] therefore desmoglein inter-



▲ **FIGURE 52-2** Desmoglein (Dsg) compensation. Triangles represent the distribution of Dsg 1 and 3 in skin and mucous membranes. Anti-Dsg 1 antibodies in pemphigus foliaceus cause acantholysis only in the superficial epidermis of skin. In the deep epidermis and in mucous membranes, Dsg3 compensates for antibody-induced loss of function of Dsg 1. In early pemphigus vulgaris, antibodies are present only against Dsg 3, which cause blisters only in the deep mucous membrane where Dsg 3 is present without compensatory Dsg 1. However, in mucocutaneous pemphigus, antibodies against both Dsg 1 and Dsg 3 are present, and blisters form in both mucous membrane and skin. The blister is deep probably because antibodies diffuse from the dermis and interfere first with the function of desmosomes at the base of the epidermis.

nalization and degradation may reflect the pemphigus antibody-induced loss of adhesion function. However, depletion, acantholysis, or both may also be dependent on antibody-mediated intracellular signaling that may or may not depend on loss of adhesion.[84] Various observations have implicated signaling, which may simply be associated with acantholysis or may be causal. Some examples follow: PV added to keratinocytes causes phosphorylation of desmoglein 1, which in turn is associated with its dissociation from plakoglobin.[85] Plakoglobin itself, which may be part of some signaling pathways, is necessary in culture for PV IgG to cause retraction of keratin filaments, which may be a marker for early acantholysis.[23] Phosphorylation of heat shock protein 27 in cells treated with PV IgG has implicated the p38MAPK signaling pathway, and inhibition of this pathway prevents cytoskeletal reorganization, presumably associated with loss of cell adhesion, in these cells.[86] Finally, blocking various signaling pathways prevents acantholysis caused by PV IgG in neonatal mice.[87] Which, if any, of these signaling mechanisms is necessary or sufficient for acantholysis, their exact involvement in causing acantholysis or whether they are activated as a result of acantholysis, remains to be determined.

Genetic Restriction of the Pemphigus Immune Response

Compared to a matched population, patients with PV have a markedly increased frequency of certain class II major histocompatibility complex (MHC) antigens. Among Ashkenazi Jews with PV, the serologically defined HLA-DR4 haplotype is predominant, whereas in other ethnic groups with PV, the DQ1 allele is more common.[88] However, the association with disease susceptibility becomes even more striking in an analysis of these MHC alleles at a genetic level to determine the amino acid sequence of the cell surface molecules that they encode. Patients with the DR4 serotype almost all have an unusual allele called *DRB1*0402*, and patients with the DQ1 serotype almost all have a rare allele called *DQB1*0503*. The protein chains encoded by these alleles vary from those encoded by the alleles found in HLA-DR4 and DQ1 controls without disease in only a few amino acids.

These MHC alleles encode cell surface molecules that are necessary for antigen presentation to the immune system; therefore, it is hypothesized that the disease-associated MHC class II molecules allow presentation of desmoglein 3 peptides to T cells.[89] Consistent with this hypothesis is the finding that certain peptides from desmoglein 3, predicted to

fit into the DRB1*0402 peptide-binding pocket, were able to stimulate T cells from patients.[90] Furthermore, in this binding pocket, if one of the negatively charged amino acids specific for the DRB1*0402 subtype of DR4 was changed to a positively charged amino acid (characteristically present in other sub-types of DR4) by site-directed mutagenesis, then the desmoglein 3 peptide could no longer be effectively presented to the T cells. Other studies have confirmed that the immune response in pemphigus is restricted to certain desmoglein peptides and immune response genes coding for antigen presentation molecules.[91–93] These studies suggest that certain populations are susceptible to PV because of the genetics of their immune response genes. However, an unexpected observation was that T cells of normal people with the DRB1*0402 or DQB1*0503 respond just as well as those of pemphigus patients to the same desmoglein 3 peptides.[89,94] Therefore, to stimulate T cells in pemphigus certain immune response genes are necessary but are not sufficient. The factor that may determine who gets pemphigus and who does not is the presence of regulatory T cells that can suppress the autoimmune response in those who do not.[89,95]

Similar, but less restricted, HLA-DR alleles are associated with PF.[96]

As opposed to the antigen-presenting immune response genes discussed above, there is more heterogeneity of the T-cell receptor variable gene usage, although there may be some restriction.[94,97]

A mouse model of PV supports the importance of both T and B cells in inducing active disease. Loss of tolerance of both the B and T cell, in this model, is necessary for disease activity to develop.[98] These findings are consistent with the importance of antigen presentation to T cells discussed above.

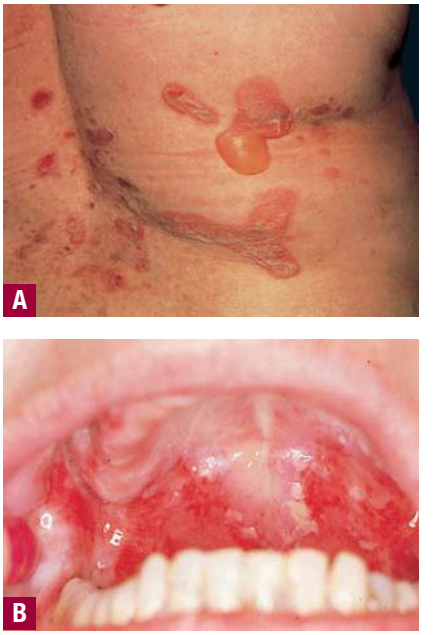
Finally, genetic cloning of monoclonal anti-desmoglein antibodies from a PV patient shows a marked genetic restriction in antibody gene usage in the anti-desmoglein antibodies.[99] This restriction is most marked for the heavy chain variable gene.

CLINICAL MANIFESTATIONS

Pemphigus Vulgaris

SKIN The skin lesions in PV are rarely pruritic, but are often painful.[1] The primary lesion of PV is a flaccid blister, which may occur anywhere on the skin surface (Fig. 52-3). Usually, the blister arises on normal-appearing skin, but it may develop on erythematous skin. Even new blisters are usually flaccid or become so within a short time. Because these blisters are fragile, intact blisters may be sparse. The most common skin lesions that occur in these patients are erosions, often painful, subsequent to broken blisters. These erosions are often quite large, as they have a tendency to spread at their periphery (Fig. 52-4). This characteristic finding can be elicited in pemphigus patients with active blistering by applying lateral pressure to normal-appearing skin at the periphery of active lesions. The result is a shearing away of the epidermis in normal-appearing areas, a phenomenon known as the *Nikolsky sign.*[100] This sign helps differentiate pemphigus from other blistering diseases of the skin (Box 52-1).

In certain patients, erosions have a tendency to develop excessive granulation tissue and crusting (Fig. 52-5); that is, these patients display more vegetating lesions. This type of lesion tends to occur more frequently in intertriginous areas, in the scalp, or on the face (see Fig. 52-5A). In pemphigus vegetans of Hallopeau, vegetating lesions are present from the outset of disease (see Fig. 52-5B). Before the advent of effective therapy for pemphigus, the prognosis for these patients was not as grave as that for patients with the more usual type of PV. In other patients (e.g., those with pemphigus vegetans of Neumann), ordinary PV erosions may tend to develop vegetations. The vegetating type of response may also appear in certain lesions that tend to be resistant to therapy and remain for long periods of time in one place. Thus, vegetating lesions seem to be one reactive pattern of the skin to the autoimmune insult of PV, with certain areas of the skin showing more of a tendency to form vegetations.



▲ **FIGURE 52-3** Pemphigus vulgaris. **A.** Flaccid blisters. (Used with permission from Lawrence Lieblich, MD.) **B.** Oral erosions.

▲ **FIGURE 52-4** Pemphigus vulgaris. Extensive erosions due to blistering. Almost the entire back is denuded. Note intact, flaccid blisters at the lower border of eroded lesions.

MUCOUS MEMBRANES In the majority of patients, painful mucous membrane erosions are the presenting sign of PV and may be the only sign for an average of 5 months before skin lesions develop (see Fig. 52-3B).[4] However, the presenting symptoms may vary according to geographic area; for example in a study from Croatia, painful oral lesions were the presenting symptom in only 32 percent of patients. Most of these patients progressed to a more generalized eruption in 5 months to 1 year; however, some had oral lesions for more than 5 years before generalization.[11] On the other hand, in Tehran, 62 percent of patients presented with oral lesions.[9] The mucous membranes most often affected are those of the oral cavity, which is involved in almost all patients with PV and is often the only mucous membrane involved (see Fig. 52-3B). Intact blisters are rare, probably because they are fragile and break easily. Scattered and often extensive erosions may appear on any part of the oral cavity, although they perhaps occur most frequently on the buccal mucosa. These erosions may spread to involve the pharynx

Box 52-1

Differential Diagnosis of Pemphigus

PEMPHIGUS SUBTYPES
- Pemphigus vulgaris
  - Pemphigus vegetans
- Pemphigus foliaceus
  - Pemphigus erythematosus
  - Endemic pemphigus foliaceus (e.g., fogo selvagem)
- Immunoglobulin A (IgA) pemphigus
  - Subcorneal pustular dermatosis
  - Intraepidermal neutrophilic dermatosis
- Paraneoplastic pemphigus

INTRAEPIDERMAL BLISTERING DISEASES WITHOUT AUTOANTIBODIES
- Familial benign pemphigus (Hailey-Hailey disease)
- Bullous impetigo, staphylococcal scalded-skin syndrome
- Blisters from herpes simplex and zoster
- Allergic contact dermatitis (e.g., rhus dermatitis)
- Epidermolysis bullosa simplex
- Incontinentia pigmenti

MOUTH ULCERS/EROSION WITHOUT AUTOANTIBODIES
- Aphthous ulcers
- Candidiasis
- Lichen planus
- Behçet disease

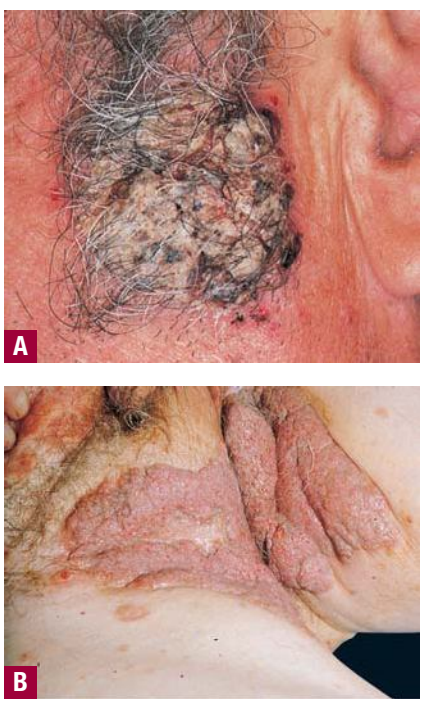
SUB-EPIDERMAL BLISTERING DISEASES WITH AUTOANTIBODIES
- Bullous pemphigoid
- Herpes gestationis
- Cicatricial pemphigoid
- Epidermolysis bullosa acquisita
- Linear IgA disease and chronic bullous disease of childhood
- Dermatitis herpetiformis
- Bullous lupus erythematosus

SUB-EPIDERMAL BLISTERING DISEASES WITHOUT AUTOANTIBODIES
- Erythema multiforme
- Toxic epidermal necrolysis
- Porphyria
- Epidermolysis bullosa

and larynx with subsequent hoarseness. Often, these erosions are so uncomfortable and, in fact, painful that the patient is unable to eat or drink adequately.

Mucous membranes in other areas may also be involved with painful erosions; these include nasal mucosa, conjunctiva, anus, penis, vagina, and labia.[9,101,102] Even the esophagus has been reported to be involved in unusual cases.[103]

Skin involvement without mucous membrane involvement in PV is unusual and accounts in one study for only 11 percent of cases.[9,104]



▲ **FIGURE 52-5** **A.** Crusted, vegetating lesions in pemphigus vulgaris. **B.** Extensive, vegetating granulomatous lesions in pemphigus vegetans.

Pemphigus Foliaceus

SKIN The characteristic clinical lesions of PF are scaly, crusted erosions, often on an erythematous base.[2,105] In more localized and early disease, these lesions are usually well demarcated and scattered in a seborrheic distribution, including the face, scalp, and upper trunk (Fig. 52-6A). The primary lesions of small flaccid blisters are often inconspicuous and difficult to find. Disease may stay localized for years, or it may rapidly progress to sometimes generalized involvement, resulting in an exfoliative erythroderma (Fig. 52-6B). Exposure to sun, heat, or both may exacerbate disease activity. Patients with PF often complain of pain and burning in the skin lesions. In contrast to patients with PV, those with PF only very rarely, if ever, have mucous membrane involvement, even with widespread disease.

The colloquial term for Brazilian endemic pemphigus, fogo selvagem (Portuguese for "wild fire"), takes into account many of the clinical aspects of this disease: the burning feeling of the skin, the exacerbation of disease by the sun, and the crusted lesions that make the patients appear as if they had been burned.

PEMPHIGUS ERYTHEMATOSUS Also known as *Senear-Usher syndrome*, pemphigus erythematosus is simply the localized form of PF. Typical scaly and crusted lesions of PF occur across the malar area of the face and in other seborrheic areas. Pemphigus erythematosus may remain localized for years, or it may evolve into more generalized PF. If there is a unique aspect of pemphigus erythematosus, it is the immunofluorescence findings noted in Immunopathology.

In addition, many patients with pemphigus erythematosus show serologic findings suggestive of systemic lupus erythematosus, especially the presence of anti-nuclear antibodies, although few patients have been reported to actually have the two diseases concurrently.[106]

Neonatal Pemphigus

Infants born to mothers with PV may display clinical, histologic, and immunopathologic signs of pemphigus.[55,107] The degree of involvement varies from none to severe enough to result in a stillbirth. If the infant survives, disease tends to remit as maternal antibody is catabolized. Mothers with PF may also transmit their autoantibodies to the fetus, but, as discussed in Pathophysiology of Acantholysis, neonatal PF occurs only rarely.[108–110] Neonatal pemphigus should be distinguished from PV and PF that occur in childhood, which are similar to the autoimmune diseases seen in adults.[111]

Drug-Induced Pemphigus

Although there are sporadic case reports of pemphigus associated with the use of several different drugs, the association with penicillamine, and perhaps captopril, is the most significant.[112] The prevalence of pemphigus in penicillamine users is estimated to be approximately 7 percent. PF (including pemphigus erythematosus) is more common than PV in these penicillamine-treated patients, although either may occur. The findings of direct and indirect immunofluorescence are positive in most of these patients. Three patients with drug-induced PF and one with drug-induced PV have been shown to have autoantibodies to the same molecules involved in sporadic pemphigus, namely, desmoglein 1 and desmoglein 3, respectively.[113] Therefore, by immunofluorescence and immu-

▲ **FIGURE 52-6** Pemphigus foliaceus. **A.** Scaly, crusted lesions on upper back. **B.** Exfoliative erythroderma due to confluent lesions.

nochemical determinations, these patients with drug-induced pemphigus resemble those with sporadic disease.

Both penicillamine and captopril contain sulfhydryl groups that may interact with the sulfhydryl groups in desmoglein 1, 3, or both, thereby causing pemphigus either by directly interfering with these adhesion molecules or, more likely, by modifying them so that they become more antigenic. The use of these drugs may also lead to a more generalized dysregulation of the immune response, allowing production of other autoantibodies such as those resulting in myasthenia gravis. Most, but not all, patients with drug-induced pemphigus go into remission after they stop taking the offending drug.

Associated Diseases

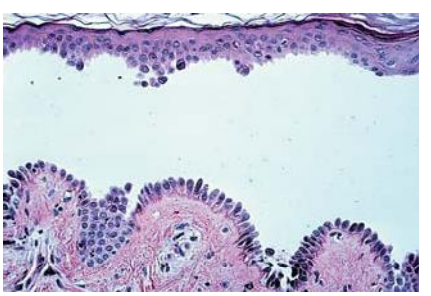
Myasthenia gravis, thymoma, or both have been associated with PV and PF.[114] Approximately one-half of associated pemphigus cases are vulgaris; one-half, foliaceus or erythematosus. Most of these data, however, were reported before the recognition of paraneoplastic pemphigus as a distinct entity. Therefore, although thymoma may clearly be associated with PV and PF, it may also be associated with paraneoplastic pemphigus (see Chap. 53). The course of myasthenia gravis and the course of pemphigus seem independent of each other. Likewise, the thymic abnormality may either precede or follow the onset of pemphigus. Thymic abnormalities include benign or malignant thymoma and thymic hyperplasia. Irradiation of the thymus or thymectomy, although clearly beneficial for myasthenia gravis, may not improve the pemphigus disease activity. Although this association is reported in at least 30 cases, the finding of thymoma or myasthenia gravis in a patient with PV or PF is still unusual.

Although very uncommon, PV or PF has been associated with bullous pemphigoid in the same patient.[115] Finally, PV has rarely evolved into PF, and vice versa, as determined by clinical, histologic, and immunochemical criteria.[116–118]

HISTOPATHOLOGY

Pemphigus Vulgaris

The characteristic histopathologic finding in PV is a suprabasilar blister with acantholysis (Fig. 52-7). Just above the basal cell layer, epidermal cells lose their normal cell-to-cell contacts and form a blister. Often, a few rounded up (acantholytic) keratinocytes are in the blister cavity. The basal cells stay attached to the basement membrane, but may lose the contact with their neighbors; as a result, they may appear to be a "row of tombstones." Usually, the upper epidermis (from one or two cell layers above the basal cells) remains intact, as these cells maintain their cell adhesion. Pemphigus vegetans shows not only suprabasilar acantholysis, but also papillomatosis of the dermal papillae and downward growth of epidermal stands into the dermis, with hyperkeratosis and scale-crust formation. In addition, pemphigus vegetans lesions may show intraepidermal abscesses composed of eosinophils.[1] Early PV lesions may show eosinophilic spongiosis.[119]



▲ **FIGURE 52-7** Histopathology of pemphigus vulgaris. Suprabasilar acantholysis. The row of tombstones.

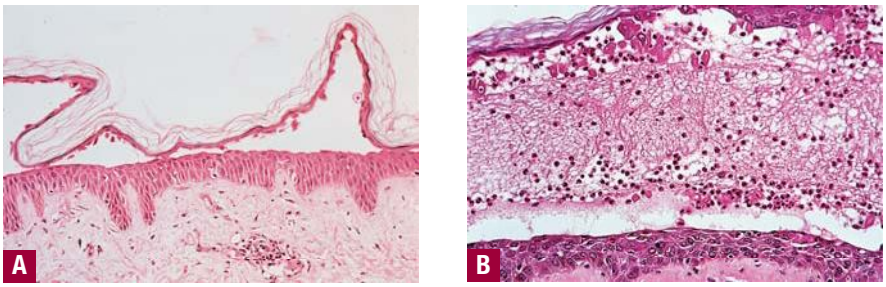
Pemphigus Foliaceus

The histopathology of early blisters in PF patients demonstrates acantholysis (loss of cell-to-cell contact) just below the stratum corneum and in the granular layer (Fig. 52-8A). The stratum corneum is often lost from the surface of these lesions. The deeper epidermis, below the granular layer, remains intact. Another frequent finding is sub-corneal pustules, with neutrophils and acantholytic epidermal cells in the blister cavity (Fig. 52-8B). These histologic findings are indistinguishable from those seen in bullous impetigo. Pemphigus erythematosus has histologic findings identical to those of PF. As in PV lesions, very early PF lesions may show eosinophilic spongiosis.[119]

PROGNOSIS AND CLINICAL COURSE

Before the advent of glucocorticoid therapy, PV was almost invariably fatal, and PF was fatal in approximately 60 percent of patients. PF was almost always fatal in elderly patients with concurrent medical problems; however, in other patients its prognosis, without therapy, was much better than PV.[120,121]

The systemic administration of glucocorticoids and the use of immunosuppressive therapy have dramatically improved the prognosis for patients with pemphigus; however, pemphigus is still a disease associated with a significant morbidity and mortality.[122,123] Infection is often the cause of death, and by causing the immunosuppression necessary in the treatment of active disease, therapy is frequently a contributing factor.[124] With glucocorticoid and immunosuppressive therapy, the mortality (from disease or therapy) of PV patients followed from 4 to 10 years is ap-



▲ **FIGURE 52-8** Histopathology of pemphigus foliaceus. **A.** Acantholysis in the granular layer. **B.** Subcorneal pustule with acantholysis.

proximately 10 percent or less, whereas that of PF is probably even less. In a more recent study of 40 patients with PV, 2 patients (5 percent) died of sepsis and 17 percent, after an average of 18 months of therapy, went into a complete and long-lasting (> 4 years, average, thought to be permanent) remission requiring no further therapy.[125] Another 37 percent of patients achieved remission but relapsed at times after therapy was stopped; most of these also eventually achieved long-lasting remissions. The remainder of patients required continual therapy. In a group of 159 patients with PV from Croatia, only approximately 12 percent went into long-term remission after therapy with glucocorticoids and immunosuppressives, but most relapsed.[11] In a study from Tehran of 1206 pemphigus patients seen over 20 years, 6.2 percent of PV and 0.2 percent of PF patients died, mostly of septicemia; only 9.3 percent were in complete remission without therapy.[9]

TREATMENT

Approach to therapy of pemphigus varies widely, even among experts.[126] It is generally agreed that PV, even if initially limited in extent, should be treated at its onset, because it will ultimately generalize and the prognosis without therapy is very poor. In addition, it is probably easier to control early disease than widespread disease, and mortality may be higher if therapy is delayed.[127]

Because PF may be localized for many years, and the prognosis without systemic therapy may be good, patients with this type of pemphigus do not necessarily require treatment with systemic therapy; the use of topical glucocorticoids may suffice. When the disease is active and widespread, however, the therapy for PF is, in general, similar to that for PV.

The systemic administration of glucocorticoids, usually prednisone, is the mainstay of therapy for pemphigus. At one time, primarily before adjuvant immunosuppressive therapy was available, very high initial doses of prednisone were recommended for therapy. Now, however, few authorities recommend such high doses, and many feel that intermediate or low doses, especially if used in combination with immunosuppressive therapy and, if necessary, with tolerance of some residual disease activity, result in fewer complications and decreased mortality.[7,124,128,129] However, some experts in pemphigus still recommend controlling active disease initially with escalating doses of prednisone.[121,130] Once disease activity is controlled, tapering prednisone to as low a dose as possible should be the goal.

Interestingly, prednisone can control blistering in as few as several days, at a time when the autoantibody titer would be unchanged. How, then, could it work to control disease? One possibility is that it may increase the synthesis of desmogleins or change their post-transcriptional modification to prolong their half-life.[131] If, as discussed in Pathophysiology of Acantholysis, pemphigus IgG depletes desmosomes of desmogleins, then prednisone could counteract this effect.

Although there are few controlled studies, most authors feel that immunosuppressive agents, such as mycophenolate mofetil (CellCept), azathioprine (Imuran), and cyclophosphamide (Cytoxan), have a steroid-sparing effect, decrease the incidence of side effects of therapy, and may increase the numbers of remissions.[32,120,122,127,132] Usually, mycophenolate mofetil or azathioprine, which has less potential adverse effects than cyclophosphamide, is the initial immunosuppressive agent.[133,134] Treatment regimens often begin with both an immunosuppressive agent and prednisone in moderate to intermediate doses, depending on disease activity, although some authors suggest first determining if the disease responds to a course of glucocorticoids alone.[32,123,129] In any case, if there are contraindications to glucocorticoid use, if the glucocorticoids do not control the disease, or if a dosage low enough to minimize the risk of steroid complications is not effective, the patient should receive adjuvant therapy, usually consisting of immunosuppressive agents.

Results obtained by using prednisone and immunosuppressive agents to treat patients with PV, although not controlled, have been impressive. For example, in a series of 29 patients treated with prednisone and azathioprine, approximately 50 percent went into clinical and serologic remission and continued off therapy for a mean follow-up of 4 years.[32] Many of these patients were considered cured. Only one patient in this study died because of complications of therapy. The disease activity of most of the other patients was well controlled.

Mycophenolate mofetil has been shown to have a rapid effect in lowering pemphigus antibody titers and to decrease disease activity, even in patients whose disease is unresponsive to azathioprine.[132–134] As it probably has fewer adverse reactions than azathioprine, it has, in some centers, replaced azathioprine as a first-line agent in treating these patients.

Cyclophosphamide, although more toxic than azathioprine or mycophenolate mofetil, is thought to be very effective in controlling severe disease, with one report of 19 of 23 patients with pemphigus achieving complete remission in a median time of 8.5 months.[135]

Early localized PV may be treated with relatively low-dose prednisone (e.g., 20 mg), often with an immunosuppressive agent.[136] The decision to use immunosuppressive agents in young patients must take into account the potential increased incidence of malignancies that might be associated with the use of these drugs, as well as the risks of infertility (especially associated with cyclophosphamide) and teratogenicity. In some patients, especially those who are elderly with limited disease or those in whom glucocorticoids are contraindicated, immunosuppressive agents alone may be used.[137] Because patients may die from complications of therapy, it is important to monitor all patients closely for potential side effects, such as infection, diabetes, leukopenia, thrombocytopenia, anemia, gastrointestinal ulcer disease, bleeding, liver and renal function abnormalities, high blood pressure, electrolyte disturbances, and osteoporosis.

There are additional, innovative therapies that are usually used when more standard treatment is not effective. For example, the intravenous, pulse administration of methylprednisolone, 250 to 1000 mg given over approximately 3 hours q24h for 4 to 5 consecutive days, can result in long-term remissions and decrease the total dose of glucocorticoids necessary to control disease.[138] Although the purpose of this therapy is to decrease the incidence of complications

of long-term steroid use, it can result in all the usual glucocorticoid complications, as well as cardiac arrhythmias with sudden death, and its use is controversial.[139] Furthermore, a controlled trial found that adjuvant oral dexamethasone pulse therapy in addition to standard therapy with prednisolone and azathioprine for PV is not beneficial.[140] It may be that simply giving divided lower doses of prednisone could accomplish the same result with fewer side effects. Intravenous pulse therapy with cyclophosphamide, with or without pulse therapy with glucocorticoids, has also been reported to result in remissions of PV.[141,142] The advantage of this therapy over that of daily cyclophosphamide has not been clearly established.

Another method of decreasing serum autoantibodies is the intravenous use of γ-globulin in high doses. It may be useful as adjuvant therapy in those whose condition does not respond to more conventional therapy.[143,144] It is thought to function by increasing catabolism of the patient's antibodies, which include the pathogenic autoantibody.[145] It seems to be effective for therapy but is expensive and requires many intravenous infusions for remission and continued infusions for maintenance of remission. There can also be significant side effects with this therapy.[146]

Another potentially very effective therapy for pemphigus that is refractory to more standard therapy is a monoclonal anti-CD20 antibody [rituximab (Rituxan)], mostly used and approved for therapy of B-cell malignancies.[147–149] In pemphigus patients, this monoclonal antibody would also presumably target B cells, the precursors of antibody-producing plasma cells. The B cell also acts to process autoantigen and present it to T cells that provide "help" in stimulating the autoantibody response. Rituximab is given as intravenous therapy once a week for 4 weeks, and such a course can be repeated in approximately 6 months. Improvement is usually seen within 1 to 2 months after the course of therapy. Most patients show at least partial remission and some show dramatic complete remissions; however, serious infections and other adverse effects may be seen, some of which may be due to concomitant use of other immunosuppressives.

Plasmapheresis is sometimes used, in combination with cyclophosphamide or another immunosuppressive agent, for severe pemphigus, or for pemphigus which is unresponsive to a combination of prednisone and immunosuppressive agents. Although one controlled study found it to be ineffective,[150] other studies have found that it both reduces serum levels of pemphigus autoantibodies and controls disease activity.[151] For maximum effectiveness, it is probably necessary to perform plasmapheresis on patients taking immunosuppressive agents to prevent the antibody-rebound phenomenon that can follow the removal of IgG.

Other potential therapies for pemphigus, used less frequently than those that have been discussed, include immunoablative therapy without stem cell rescue; the administration of cyclosporine, gold, antimalarials, or dapsone; and extracorporeal photochemotherapy.[113,152–154]

All in all, there has been a tremendous advance in the armamentarium of therapies for pemphigus since the time before the development of glucocorticoids when PV was a fatal disease. Thanks to these advances, the "row of tombstones" seen in the pathology of PV no longer alludes to its prognosis.

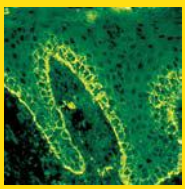
CHAPTER 53

Paraneoplastic Pemphigus

Grant J. Anhalt
Carlos H. Nousari

Paraneoplastic pemphigus (PNP) is an autoimmune disorder that is almost always linked to an underlying lymphoproliferative disorder. These features define it: (1) Painful stomatitis and a polymorphous cutaneous eruption with lesions that may be blistering, lichenoid, or resemble erythema multiforme. (2) Histologic findings that reflect the variability of the cutaneous lesions, showing acantholysis, lichenoid, or interface change. (3) Direct immunofluorescence demonstrating deposition of immunoglobulin G (IgG) and complement in the epidermal intercellular spaces, and often granular/linear complement deposition along the epidermal basement membrane zone. (4) Serum autoantibodies that bind the cell surface of skin and mucosae in a pattern typical for pemphigus, but in addition, bind to simple, columnar, and transitional epithelia. (5) These serum autoantibodies identify desmogleins 1 and 3, but additionally identify members of the plakin family of epithelial proteins, such as desmoplakins, envoplakin, and periplakin.[1] The disease is associated, in the majority of cases, with non-Hodgkin lymphoma (NHL), chronic lymphocytic leukemia (CLL), and Castleman disease. There is no regularly effective treatment and most patients die from complications of the disease, including pulmonary involvement with respiratory failure.

PARANEOPLASTIC PEMPHIGUS AT A GLANCE



- Rare complication of malignancy, most commonly non-Hodgkin lymphoma, chronic lymphocytic leukemia, or Castleman disease.
- Painful, erosive stomatitis and polymorphous cutaneous lesions that may be blistering and erosive (resembling erythema multiforme), morbilliform, or lichenoid.
- Serum autoantibodies directed against plakin proteins that are detected by indirect immunofluorescence against rodent bladder epithelium.
- High mortality rate, with death due to sepsis, complications of treatment, or bronchiolitis obliterans.
- No consistently effective therapy, but some success with the combined use of rituximab, systemic corticosteroids, and other immunosuppressive agents.

EPIDEMIOLOGY

The incidence of the disease is unknown, but it is less common than pemphigus vulgaris or foliaceus (see Chap. 52). In an analysis of adverse event reporting in 100,000 patients with known NHL and CLL, there were 12 cases of PNP. Of note, only three of these cases were identified by the reporting physician as such, and the remainder were identified only by retrospective data analysis. That implies that the majority of cases are still not properly diagnosed. The most common misdiagnoses applied in this series were erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis (TEN), and drug reaction.

ETIOLOGY AND PATHOGENESIS

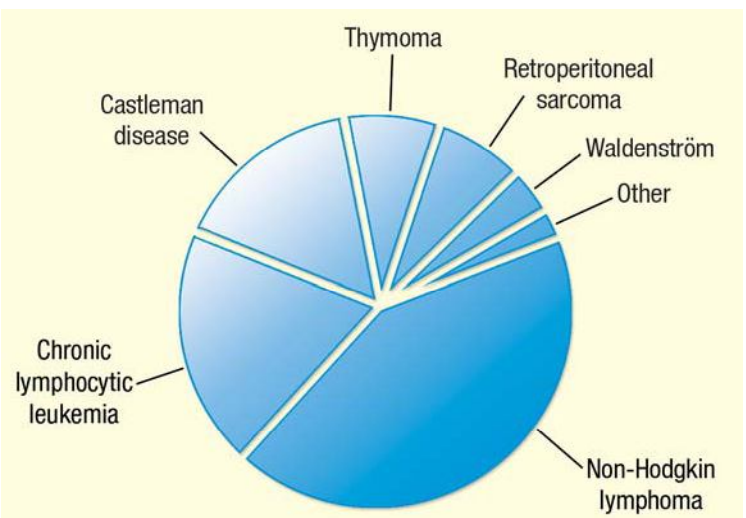
In almost all cases, this syndrome is associated with a limited number of lymphoproliferative neoplasms. The approximate frequency of specific neoplasms has been estimated, based on 140 cases of PNP diagnosed and confirmed by immunoprecipitation demonstration of the characteristic autoantibody profile, to be 44 percent NHL, 19 percent CLL, 16 percent Castleman disease (giant follicular hyperplasia), 8 percent thymoma (malignant and benign), 7 percent sarcomas that are retroperitoneal and often poorly differentiated, 4 percent Waldenström macroglobulinemia, and in 2 percent the neoplasms were too poorly differentiated to categorize (Fig. 53-1). The majority of cases are associated with NHL and CLL, but the disproportionate representation of Castleman disease is notable because of the rarity of this disorder. The association with Castleman is even more striking in pediatric cases, where it is the underlying neoplasm in almost all cases.[2] Before the description of PNP there were many cases of Castleman disease associated with atypical forms of pemphigus, and we suspect most were cases of PNP. Archived clinical material was available from one such case, which subsequently confirmed that the patient had autoantibodies specific for PNP.

With very rare exceptions, more common cancers, such as adenocarcinomas of breast, bowel, and lung, or basal cell and squamous cell carcinoma of skin have not been associated with PNP. There are a few reports of PNP occurring with tumors such as squamous cell carcinoma, but most of these diagnoses have not been confirmed by immunochemical testing, so the association remains unproven.

The mechanisms by which these tumors induce autoimmunity against epithelial proteins remains speculative. One hypothesis states that the tumors constitutively or anomalously express epithelial proteins. These proteins are targeted by the antitumor immune response that cross-reacts with normal constitutive epithelial proteins of the host. This mechanism occurs in several neurologic paraneoplastic syndromes.[3] This antitumor immune response may be initiated by reactivity against plakin proteins, and the antitumor immune response may cross-react with normal constitutive proteins of epithelia. To date, there is no evidence to support this hypothesis.

It is more likely that this autoimmune disease is a result of more complex interactions between the tumor cells and the immune system. There is some evidence that dysregulated cytokine production by tumor cells drives the development of autoimmunity. Patients with PNP have evidence of markedly elevated levels of interleukin 6 (IL-6).[4] It has been observed that in a subset of cases of NHLs,[5] CLL, and Castleman tumors, the tumor cells secrete massive amounts of IL-6 in vitro. IL-6 is known to promote B-cell differentiation and to drive immunoglobulin production, and dysregulated IL-6 production has been implicated in certain autoimmune diseases. Castleman tumors are known to be associated with other autoimmune phenomena such as myasthenia gravis and autoimmune cytopenias, and these patients also have high serum levels of IL-6. Symptoms attributable to Castleman tumors are routinely reversed by complete excision of the affected node(s), and, coincidentally, serum IL-6 levels revert to normal. Administration of anti–IL-6 monoclonal antibodies also effectively reverses systemic manifestations of Castleman disease and is currently being studied in clinical trials.[5]

It had also been proposed that the lymphoid tumor itself may produce autoantibody. Cultures of Castleman tumors have been shown to contain B cells that produce specific autoantibody.[6] However, Castleman tumors are unique in that they are nonclonal neoplasms,



▲ **FIGURE 53-1** Tumors associated with paraneoplastic pemphigus.

and these studies showed the expansion of several immunologically active B-cell clones within the tumors. In Waldenström macroglobulinemia, the autoantibody is not of IgM origin, but is polyclonal and IgG, showing that the tumor cells do not produce the autoantibody.

Almost all patients have autoantibodies against desmogleins, demonstrable by enzyme-linked immunosorbent assay, and when the desmoglein autoantibodies from these patients are injected into neonatal mice, acantholytic skin lesions are induced.[7] However, none of features of the disease that suggest cell-mediated autoimmunity is recreated by immunoglobulin injections. No other internal organs are involved, and there is no lymphocyte-mediated cell damage. This is also an indication that humoral immunity alone reproduces features of acantholysis, but passive transfer of autoimmune cells from these patients may be necessary to reproduce the complete spectrum of the disease in animals.

CLINICAL FINDINGS

History

Cutaneous Lesions

The most constant clinical feature of the disease is the presence of intractable stomatitis (Fig. 53-2A,B). This is the earliest presenting sign, and after treatment it is the one feature that persists throughout the course of the disease and is extremely resistant to therapy. This finding is so consistent that the diagnosis should not be considered if stomatitis is absent.

This stomatitis consists of erosions and ulcerations that can affect all surfaces of the oropharynx. The lesions differ from those seen in pemphigus vulgaris in that they show more necrosis and lichenoid change. They also preferentially localize to the lateral borders of the tongue, and characteristically extend onto and involve the vermilion of the lips. Occasionally, oral lesions are the only manifestation of the disease.

The cutaneous lesions of PNP are quite variable, and different morphologies may occur in an individual patient according to the stage of the disease (see Fig. 53-2C,D). The initial patients reported with the syndrome had episodes of waves of blistering affecting the upper trunk, head and neck, and proximal extremities. These lesions consisted of blisters that ruptured easily, leaving erosions. The blisters on the extremities were sometimes quite tense, resembling those seen in bullous pemphigoid, or they had surrounding erythema, clinically resembling erythema multiforme (see Fig. 53-2D). On the upper chest and back, confluent erosive lesions can develop, producing a picture resembling TEN. The similarity of the mucocutaneous features to erythema multiforme and TEN explains why this is the most common differential diagnosis for PNP. However, it is important to note that erythema multiforme and TEN are self-limited events that evolve and resolve over several weeks, whereas PNP is a relentlessly progressive disease that continuously evolves over months.

▲ **FIGURE 53-2** **A.** Extensive erosions involving the vermillion of the lips in a patient presenting with paraneoplastic pemphigus and an occult lymphoma. The characteristic severe stomatitis, accompanied by polymorphous cutaneous lesions, is the most consistent feature of the disease. **B.** Painful ulcerations tend to localize to the lateral border of the tongue. **C.** Lesions of the trunk from the same patient pictured in **A**. Erythematous macules and papules coalesce and become erosive on the upper chest as the cutaneous lesions evolve. **D.** Lesions from the forearm of the same patient. These lesions clinically resemble erythema multiforme, but biopsy shows a mix of individual cell necrosis, interface change, and acantholysis.

Cutaneous lichenoid eruptions are very common, and they may be the only cutaneous signs of the disease or may develop in lesions that had previously been blistered. When cutaneous lichenoid lesions are present, severe stomatitis is also invariably present. In the chronic form of the disease and after treatment, this lichenoid eruption may predominate over blistering on the cutaneous surface. Both blisters and lichenoid lesions affecting the palms and the soles as well as the paronychial tissues are common and help to distinguish this from pemphigus vulgaris, in which acral and paronychial lesions are uncommon.

There are a small number of patients who appear to have PNP but who do not have demonstrable circulating autoantibodies.[8] These patients tend to have predominantly lichenoid skin and mucosal lesions, but behave in every other way like antibody-positive patients. They have the same underlying neoplasms, and frequently develop bronchiolitis obliterans. Because the definition of the disease relies so heavily on demonstration of the specific autoantibody markers, further study is required to know how to classify these patients. For now, they are called the *lichenoid variant of paraneoplastic pemphigus*.

The disease has also been identified in a horse and two dogs. In animal spe-

cies, the disease has the same associated neoplasms and clinical outcomes.[9]

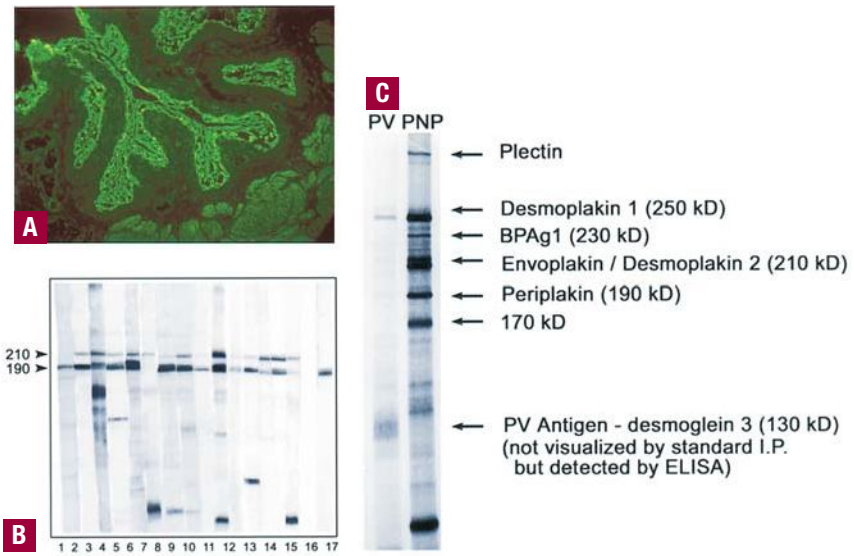
Related Clinical Findings

PNP is the only form of pemphigus that has involvement of non-stratified squamous epithelium. Approximately 30 percent to 40 percent of cases develop pulmonary injury, often with a fatal outcome.[10] The earliest symptoms are progressive dyspnea associated initially with an absence of findings on chest radiography. Pulmonary functions studies show airflow obstruction, involving large and small airways. Inflammation of the large airways evolves and is evidenced by endoscopic biopsy showing acantholysis of bronchial respiratory epithelium. Pulmonary function deteriorates in most cases despite immunosuppressive therapy, and radiologic, histologic, and functional changes characteristic of bronchiolitis obliterans develop.

LABORATORY TESTS

The key finding is the serologic identification of polyclonal IgG autoantibodies against plakin proteins and, in most cases, desmogleins 1 and 3. The plakins are a group of sequence-related proteins that form the intracellular plaque of desmosomes and hemidesmosomes, and mediate attachment of cytoskeletal intermediate filaments to transmembrane adhesion molecules such as the desmogleins (see Chap. 51). Autoantibodies against these proteins are the most characteristic surrogate markers for the disease. The pattern of antigens recognized by individual patients shows considerable variability, but the most characteristic and consistently recognized plakin antigens are envoplakin[11] and periplakin[12] (210 and 190 kd, respectively; Fig. 53-3). The next most frequently detected are antibodies against desmoplakin I and desmoplakin II (250 and 210 kd, respectively). Less commonly, patients recognize bullous pemphigoid Ag 1 (230 kd), plectin, and plakoglobin. The identity and frequency of an antigen band at 170 kd are not well defined. PNP patients may also have clinical and serologic evidence of other autoimmune phenomena such as myasthenia gravis and autoimmune cytopenias (see Fig. 53-3).

To screen for PNP autoantibodies, one can test for IgG autoantibodies by indirect immunofluorescence reactive with rodent urinary bladder epithelium. A positive result implies the presence of plakin autoantibodies; however, the sensitivity and specificity of this serologic test are only approximately 75 percent and 83 percent, respectively.[13] More specific and sensitive tests include immunoblotting against epidermal cell extracts that can effectively detect antibodies against envoplakin, periplakin, desmoplakin, and immunoprecipitation, using radiolabeled keratinocyte extracts, which can detect antibodies against any of the plakin proteins.



▲ **FIGURE 53-3** Diagnosis of paraneoplastic pemphigus (PNP) depends on the demonstration of antiplakin antibodies. **A.** This can be accomplished by indirect immunofluorescence of patient serum on rodent urinary bladder demonstrating binding of immunoglobulin G to the cell surface of transitional epithelial cells. A positive result implies the presence of anti-plakin antibodies. This technique, although easily performed, has the lowest sensitivity and specificity. **B.** Immunoblotting against epidermal cell extracts is much more sensitive and specific. This shows detection of envoplakin (210 kd) and/or periplakin (190 kd) in 15 patients with PNP. Lane 16 is a normal control, and lane 17 shows a monoclonal antibody against periplakin. This technique uses denatured antigen extracts, so it does not reliably detect some of the PNP antigens, but antibodies against the most characteristic plakin antigens, envoplakin and periplakin, are easily detected. **C.** Immunoprecipitation using radiolabeled, nondenatured epidermal extracts and serum from a patient with PNP and pemphigus vulgaris (PV). In this case, the PNP patient's serum identifies all of the plakin antigens. Envoplakin and desmoplakin II migrate as a doublet at 210 kd. This technique is the most sensitive and specific test for demonstration of anti-plakin antibodies in PNP, but has limited availability. Although this technique readily detects the anti-plakin antibodies, desmoglein 3 is not always efficiently identified, and this is best shown by using enzyme-linked immunosorbent assay (ELISA).

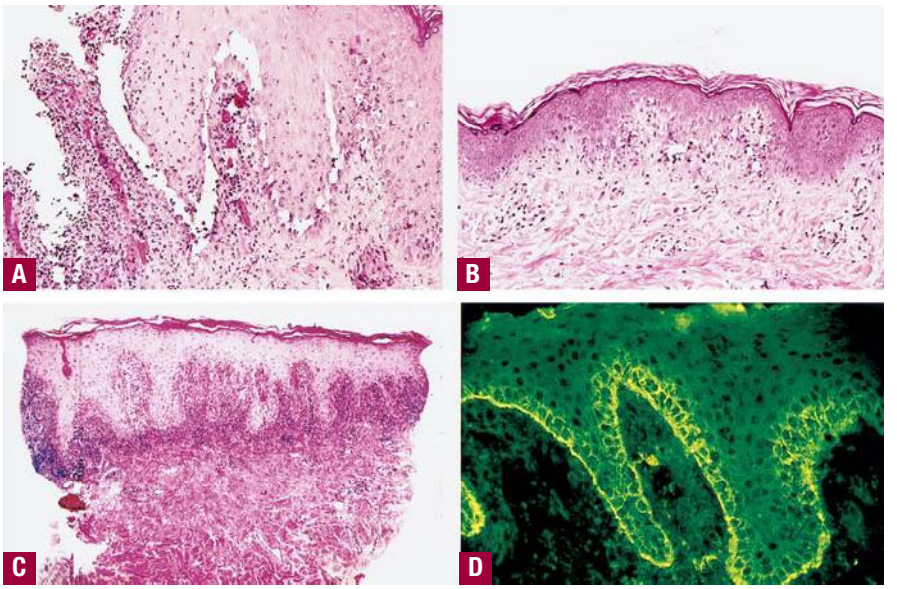
The PNP autoantibody profile is more complex than that observed in pemphigus vulgaris or foliaceus, where there are autoantibodies produced only against the desmogleins. The humoral immunity in PNP may represent an example of epitope spreading in which patients develop autoantibodies against structurally related plakin proteins and structurally unrelated transmembrane cell surface proteins (the desmogleins) that are physically linked to the plakin proteins in the desmosome and hemidesmosome.

Histopathology

The histopathology of PNP is distinctive from pemphigus vulgaris and foliaceus for two reasons. First, because the lesions can be clinically very polymorphous, there is substantial variability in the histologic findings.[14] Second, findings due to cell-mediated cytotoxicity are frequently observed.

Because of the severe mucositis, many biopsies of oral lesions yield non-specific changes of inflammation and ulceration. If one can biopsy perilesional epithelium, a lichenoid mucositis with variable degrees of individual cell necrosis and suprabasilar acantholysis can be observed.

When evaluating biopsies from skin lesions, one must recognize that lesions with different clinical morphologies yield differing histologic findings. In noninflammatory cutaneous blisters, suprabasilar acantholysis is expected to be more prominent than the interface/lichenoid change (Fig. 53-4A). When erythematous macules and papules are sampled, interface and lichenoid dermatitis is predominant (see Fig. 53-4B,C). Lesions with a mixed clinical pattern also show mixed histologic features of concomitant suprabasi-



▲ **FIGURE 53-4** **A.** Histopathology of a blistering cutaneous lesion in paraneoplastic pemphigus. This demonstrates the characteristic presence of vacuolar interface change and suprabasilar acantholysis. [Hematoxylin and eosin (H&E), 200×.] **B.** Macular and papular lesions may show just vacuolar interface change. (H&E, 100×.) **C.** Lichenoid lesions demonstrate lichenoid infiltrates on histologic examination. (H&E, 40×.) The presence of these varied histologic findings help differentiate paraneoplastic pemphigus from pemphigus vulgaris. **D.** Direct immunofluorescence can be negative in a significant number of cases, but when positive, the most characteristic changes are those of deposition of immunoglobulin G and complement components on both the surface of basilar and suprabasilar keratinocytes and along the epidermal basement membrane zone. (Immunofluorescence with fluoresceinated anti-immunoglobulin G, 200×.)

lar acantholysis and interface/lichenoid dermatitis.

There is also observed variability of the interface and lichenoid dermatitis. The spectrum of changes can include: (1) individual keratinocyte necrosis with lymphocytic infiltration into the epidermis, reminiscent of that seen in erythema multiforme or graft-versus-host disease; (2) vacuolar interface change with sparse lymphocytic infiltrate of the basilar epithelium, resembling cutaneous lupus erythematosus or dermatomyositis; and (3) a thick lichenoid band along the dermal-epidermal junction similar to that seen in lichen planus. Although most of the specimens show a complex overlap of histologic patterns, there is a relatively good correlation between the clinical and the predominant histologic pattern.

The histopathologic variability of this disease may be related to the fact that it is a presumed antitumor immune response. If this speculation is correct, one would expect to observe a combination of both humoral and cell-mediated immunity that is aberrantly directed against normal epithelium. In such a setting, one would expect to see changes of the sort described in the previous paragraph. This degree of cell-mediated immunity is not seen in pemphigus vulgaris or foliaceous (see Chap. 52); hence the unique histopathologic features, and, presumably, the unique clinical features as well. The presence of T-cell mediated epithelial cytotoxicity has been recently demonstrated in histologic studies.[15]

Immunopathology

Patients should have evidence of IgG autoantibodies bound to the cell surface of affected epithelium by direct immunofluorescence. However, false negatives are more common in PNP than in pemphigus vulgaris and repeated biopsies may be necessary to demonstrate this finding. In a minority of cases, one might also see a combination of both cell surface and basement membrane zone deposition of IgG and complement components, but the absence of this combined cell surface/basement membrane zone staining does not negate the diagnosis (see Fig. 53-4D).

Special Tests

Approximately one-third of patients have an occult malignancy at the time they develop PNP. Neoplasms that would not be detected by routine complete blood count, serum chemistries, and physical examination are most likely to be intra-abdominal lymphoma, intrathoracic or retroperitoneal Castleman tumors, or retroperitoneal sarcomas. The most effective and efficient method for screening for these tumors is either computer-aided tomography or magnetic resonance imaging of the body from the neck to the base of the bladder. Other studies, such as endoscopy, are not required.

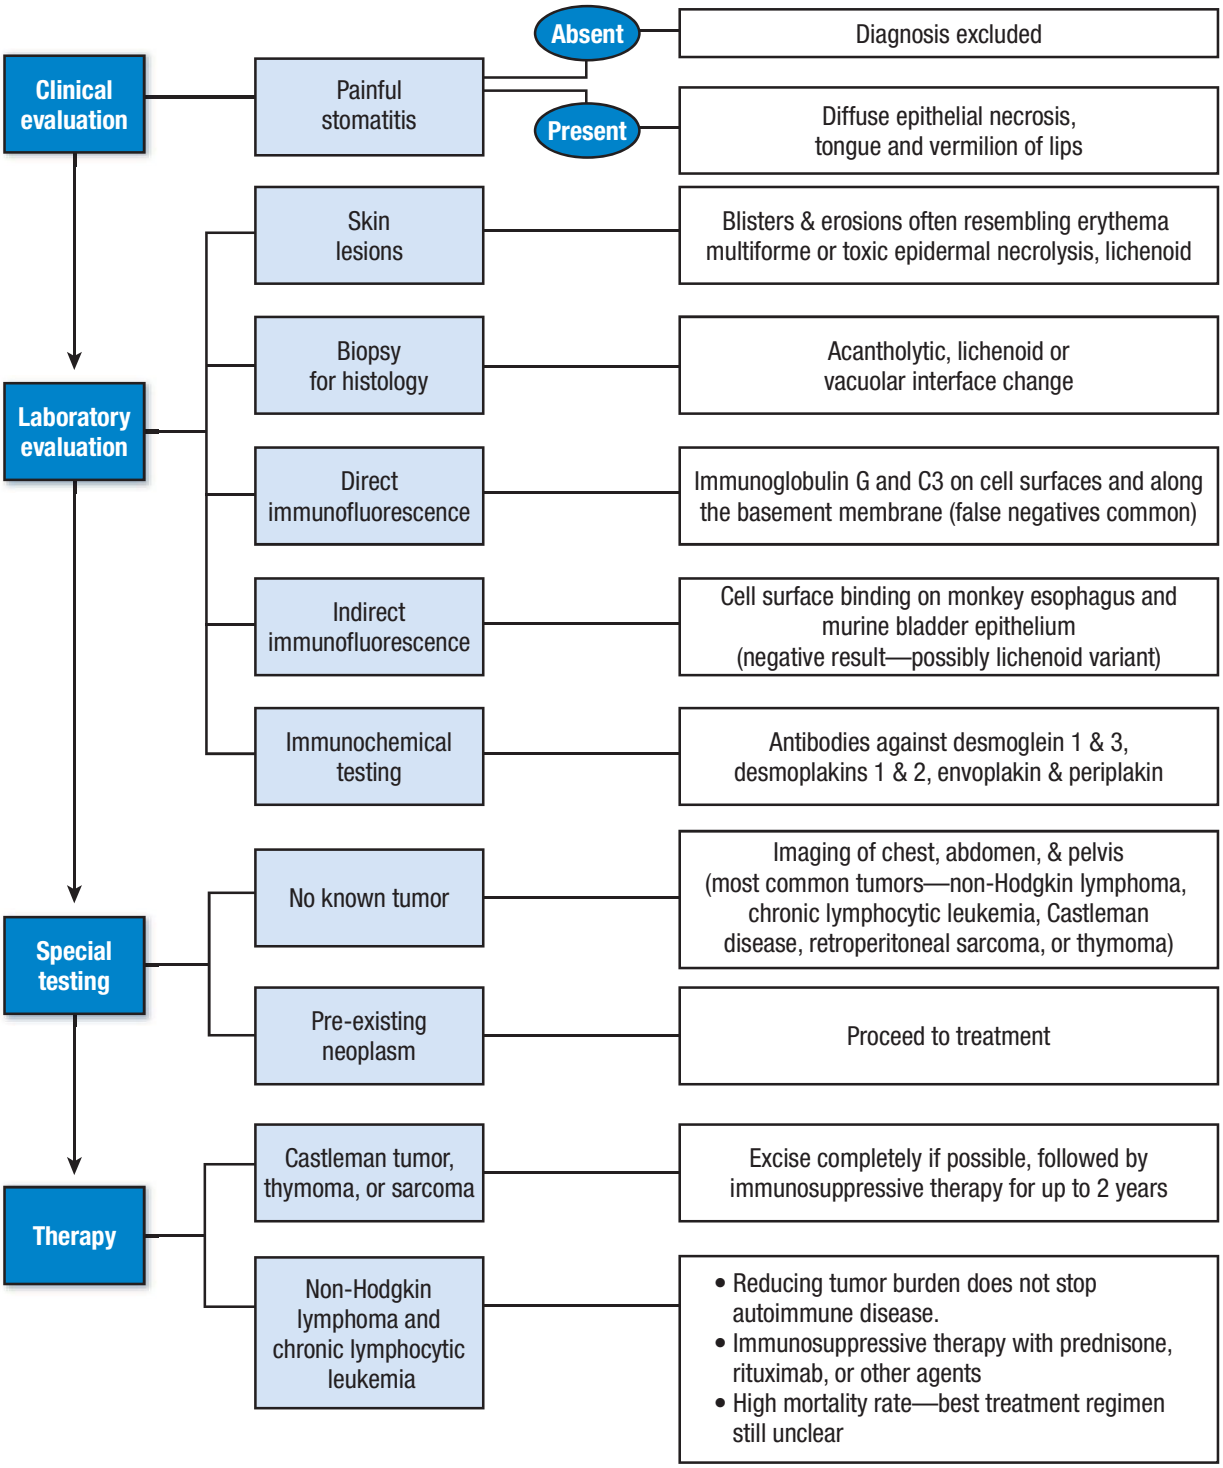
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis can best be made if the algorithm shown in Fig. 53-5 is followed. The clinical differential diagnosis is summarized in Box 53-1.

PROGNOSIS AND CLINICAL COURSE

It is not known why PNP is so refractory to the type of immunosuppressive treatments that are usually effective in pemphigus vulgaris and other autoimmune diseases.

In those patients who do succumb, death has been attributed in individual cases to multiple factors, including sepsis, gastrointestinal bleeding, "multiorgan failure," and respiratory failure. Patients with autoimmune disease associated with B-cell neoplasms are known to have a high frequency of autoimmune cytopenias, and some fatal episodes of sepsis are suspect to have occurred because of sudden and unexplained neutropenia, possibly due to this mechanism. Respiratory failure is a common terminal event. The development of shortness of breath with obstructive disease progressing to bronchiolitis obliterans is a terminal pathway in most cases. Because these patients have autoantibodies that react with desmoplakins, and because desmoplakins are present in respiratory epithelium, respiratory failure may be due to autoantibody-mediated injury to bronchial epithelium, with plugging of terminal bronchioles, resulting in airflow obstruction and ventilation/perfusion abnormalities. Additionally, direct damage to alveolar epithelium could cause a diffusion barrier and subsequent intractable hypoxia. One autopsy study showed an absence of autoantibodies and a marked infiltration of bronchioles with cytotoxic T cells in a patient who died from PNP and bronchiolitis obliterans. This shows that there may be similar complex humoral and cell-mediated autoimmune injury to the lung, similar to what is seen in the skin. The pulmonary injury does not respond well to medical treatment, and



▲ **FIGURE 53-5** Approach to a patient with paraneoplastic pemphigus.

the development of shortness of breath and hypoxia in a patient with this syndrome is an ominous prognostic sign.

In patients with malignant neoplasms there is no definite correlation between tumor burden and the activity of the autoimmune syndrome. Treatment of the primary malignancy does not affect the activity of the autoimmune disease. It seems that once the process is initiated by the malignancy, the autoimmunity progresses independently. An example of the disconnect between tumor burden and autoimmunity is found in the case reported by Fullerton et al.,[16] in which PNP occurred after successful autologous bone marrow transplantation for NHL. This patient was free of detectable tumor burden at the time of his death, but died from pulmonary injury secondary to PNP. It is notable that the patient underwent autologous bone marrow transplantation, and therefore received his own memory T cells, or possibly individual malignant lymphoid cells that were not detectable by routine autopsy methods.

TREATMENT (Box 53-2)

Individuals with benign or encapsulated tumors such as Castleman tumors or thymoma should have them surgically

Treatments for Paraneoplastic Pemphigus

	DRUG	USUAL DOSE	OTHER DOSING
First line	Prednisone	0.5–1.0 mg/kg	Methylprednisolone, 1000 mg IV daily × 3 days
	Rituximab	375 mg/m^2 IV weekly × 4 wk	1000 mg IV weekly × 2 wk
	Daclizumab	2 mg/kg IV weekly × 4 wk, then every other week indefinitely	
Second line	Cyclosporine	5 mg/kg daily	
	Cyclophosphamide	2.5 mg/kg daily	
	Mycophenolate mofetil	1500 mg PO bid	
	High-dose IV immunoglobulin	2 g/kg IV, repeat q 3–4 wk	
	Plasmapheresis	Every other day for six total treatments	

excised. If the entire lesion is removed, the disease generally improves substantially or goes into complete remission. The remission of the autoimmune disease may take 1 to 2 years after surgery, so continued immunosuppression during this period is required. The usual treatment involves combined use of prednisone and rituximab.[17] In pediatric cases with respiratory disease, the persistent autoimmunity immediately postsurgery can cause ongoing pulmonary injury, and lung transplantation might be required for long-term survival.[18]

In patients with malignant neoplasms, there is no consensus regarding a therapeutic regimen that is consistently effective. Although there are a couple of individual reports of long-term survivors, almost all patients with NHL or CLL succumb in a period of 1 month to 2 years after diagnosis. Oral corticosteroids in a dose of 0.5 to 1.0 mg/kg produce partial improvement, but not complete resolution of lesions. Although cutaneous lesions respond more quickly to therapy, the stomatitis is generally quite refractory to any form of therapy. In addition to corticosteroids, many other agents have been tried in individual cases, but none has proven to be particularly effective. Methods that have been tried and that have frequently been unsuccessful include immunosuppression with cyclophosphamide, mycophenolate mofetil or azathioprine, gold, dapsone, plasmapheresis, and photopheresis. A small number of patients have shown a good response to combination treatment directed at both humoral and cell-mediated autoimmunity. These patients received oral prednisone, rituximab, and daclizumab, a monoclonal antibody against CD 25, the high affinity IL-2 receptor. This appears to be a less toxic way of downregulating both humoral and cell-mediated autoimmunity, with promising early results.

PREVENTION

There is no known intervention that may prevent the development of PNP in a patient with a known lymphoid malignancy. Although there have been individual case reports of PNP perhaps being triggered by certain drugs, radiation therapy, or cytokine administration, it is still not clear that any of these treatments triggered the autoimmune disease, and it appears more likely that the neoplasm itself triggers the autoimmunity.

CHAPTER 54

Bullous Pemphigoid

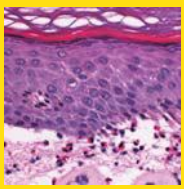
John R. Stanley

Walter Lever was a pioneer in classifying bullous pemphigoid as a disease different from pemphigus with its own distinctive clinical and histologic features.[1] This was important because at the time pemphigus vulgaris usually was fatal, whereas bullous pemphigoid had a comparatively good prognosis. This classification of bullous pemphigoid and pemphigus was confirmed and fully justified by the distinctive immunopathologic features of these diseases discovered approximately 12 years later.[2,3]

EPIDEMIOLOGY

The majority of patients with bullous pemphigoid are older than 60 years old at the age of onset, with a peak incidence in the 80s and older.[4,5] Although bullous pemphigoid does occur rarely in children,[6] reports earlier than approximately 1970 (when the use of immunofluorescence for diagnosis became more widespread) were inaccurate because these most likely included children with chronic bullous disease of childhood, which is now differentiated from bullous pemphigoid by the presence of immunoglobulin A (IgA), rather than IgG, at the basement membrane zone. There is no known ethnic, racial, or sexual predilection for developing bullous pemphigoid. The incidence of bullous pemphigoid is estimated to be seven per million per year in both France and Germany, and 14 per million per year in Scotland.[5,7,8] However, the incidence in Scottish men older than 85 years old is reported as 472 cases per million per year.

BULLOUS PEMPHIGOID AT A GLANCE



- Usually occurs in elderly patients.
- Mortality 6 percent to 40 percent in 1 year.
- Pruritic urticarial lesions and tense large blisters. Oral mucous membrane erosions in minority of patients.
- Pathology shows sub-epidermal blisters with eosinophils.
- Direct immunofluorescence shows C3 and immunoglobulin G at epidermal basement membrane, indirect immunofluorescence shows anti–basement membrane immunoglobulin G in serum.
- Autoantigens are proteins in the keratinocyte hemidesmosome, a basal cell-basement membrane adhesion structure.
- Therapy includes topical and systemic corticosteroids and immunosuppressives.

ETIOLOGY AND PATHOGENESIS

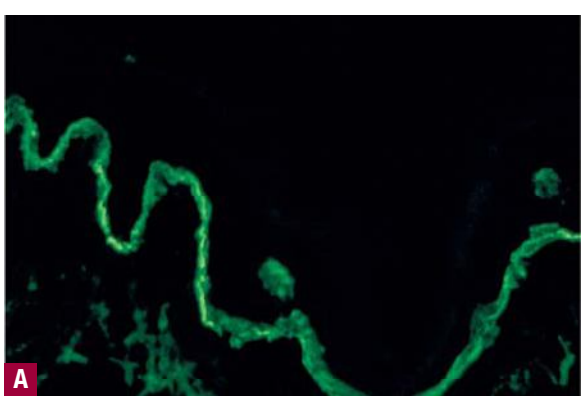
Electron Microscopy

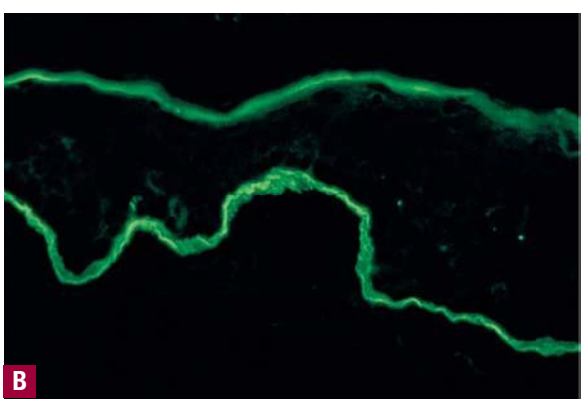
Ultrastructural studies demonstrate that early blister formation in bullous pemphigoid occurs in the lamina lucida, between the basal cell membrane and the lamina densa.[9] With blister formation, there is loss of anchoring filaments and hemidesmosomes. With degranulation of infiltrating leukocytes, there is fragmentation and ultimate loss of the lamina densa.[10] In addition, degranulation of mast cells near the epidermal basement membrane has been observed both by light and electron microscopy.[11]

Immunopathology

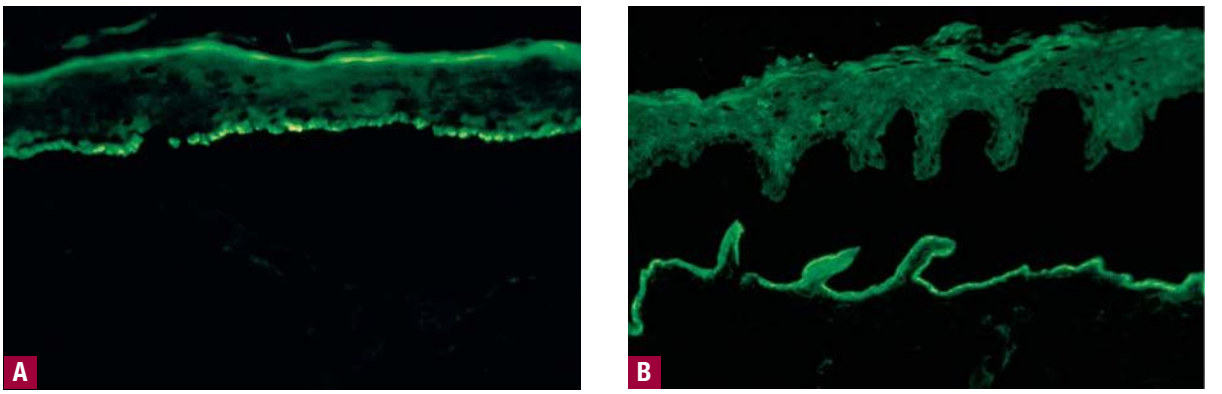
Direct immunofluorescence of perilesional skin from pemphigoid patients reveals immunoreactants deposited in a linear pattern at the epidermal basement membrane.[2,3] C3 is detected in almost all patients, sometimes as the sole immunoreactant; however, IgG is also detected in most patients (Fig. 54-1A).[12–14]

Indirect immunofluorescence indicates that approximately 70 percent to 80 percent of patients with bullous pemphigoid have circulating IgG that binds to the basement membrane of normal stratified squamous epithelia, such as human epidermis or monkey esophagus (see Fig. 54-1B).[12–15] Most patients with circulating anti–basement membrane IgG also have anti–basement membrane IgE in their sera.[16–18] If the immunofluorescence substrate is incubated first in 1 *M* NaCl to separate the epidermis from the dermis at the lamina lucida, then an even higher percentage of patients will have detectable circulating antibody.[19,20] In addition to being more sensitive, the other advantage of this 1 *M* NaCl-split substrate is that bullous pemphigoid antibodies bind to the roof of the artificially induced blister (i.e., the bottom of the basal cells) and thus can be differentiated from the antibodies of patients with epidermolysis bullosa acquisita (EBA); their antibodies bind the base (i.e., dermal side; Fig. 54-2). In contrast to pemphigus, in bullous pemphigoid the indirect immunofluorescence





▲ **FIGURE 54-1** Immunofluorescence in bullous pemphigoid. **A.** Direct immunofluorescence of perilesional skin shows a linear band of C3 (×340). **B.** Indirect immunofluorescence shows a linear pattern of immunoglobulin G binding to the epidermal basement membrane of normal skin (×340).



▲ **FIGURE 54-2** Indirect immunofluorescence on normal skin previously incubated in 1 *M* NaCl. **A.** Immunoglobulin G (IgG) from bullous pemphigoid serum binds to the roof of the artificial blister (×330). **B.** IgG in epidermolysis bullosa acquisita serum binds to the base (×215).

antibody titer does not usually correlate with disease extent or activity.[21]

In addition to C3, other components of both the classical and alternative complement pathways and the complement regulatory protein β1H are deposited at the epidermal basement membrane zone in bullous pemphigoid patients.[22–24] Activated complement components are found in the blister fluid of these patients, and in vitro complement fixation immunofluorescence assays indicate the ability of bullous pemphigoid sera to fix complement components of the classical and alternative pathways to the epidermal basement membrane. These studies suggest that bullous pemphigoid IgG causes complement activation by the classic pathway, with activation of the alternative pathway by the C3 amplification mechanism.

Pemphigoid Antigens

Immunoelectron microscopic studies have localized bullous pemphigoid antigen in the hemidesmosome, an adhesion junction important in anchoring the basal cell to the basement membrane.[25,26] Autoantibodies bind both inside the cell to the plaque of the hemidesmosome and outside the cell to the extracellular face of the hemidesmosome.

Molecular characterization of bullous pemphigoid antigen by immunochemical methods revealed the unexpected finding that autoantibodies from these patients bind two distinct molecules.[27] Most bullous pemphigoid patients have antibodies against a 230-kd molecule.[28–30] Cloning of the complementary DNA encoding this molecule (now called *BPAG1* or *BPAG1e*) indicated that it belongs to a gene family that includes desmoplakin I, a desmosome plaque protein that is important in anchoring keratin intermediate filaments to the desmosome (see Chap. 51).[31,32] BPAG1e has been localized ultrastructurally to the plaque of the hemidesmosome, exactly where keratin intermediate filaments insert.[33] Further proof that the function of BPAGle is to anchor keratin intermediate filaments to the hemidesmosome was obtained by analysis of a mouse that was genetically engineered with a targeted deletion of this molecule.[34] This mouse showed fragility of basal cells due to collapse of the keratin filament network but no epidermal-dermal adhesion defect, suggesting that bullous pemphigoid antibodies do not act by inhibiting the function of BPAG1e. In fact, because BPAG1e is inside the cell, it is unclear if patient autoantibodies normally have access to it. Interestingly, an alternatively spliced form of BPAG1e is expressed in neural tissue. Now termed *BPAG1n*, this form stabilizes the cytoskeleton of sensory nerves,[35,36] just as BPAG1e stabilizes the cytoskeleton of epidermal cells.

Immunochemical studies have also revealed that almost all patients with bullous pemphigoid, as well as patients with herpes gestationis, have autoantibodies against a 180-kd molecule now called *BPAG2* or *type XVII collagen*.[37–39] The complementary DNA encoding the BPAG2 molecule has been cloned, and the expressed protein is a transmembrane molecule with a collagenous extracellular domain.[40] Antibodies against BPAG2 localize it as a transmembrane molecule at the hemidesmosome, and cell biologic studies indicate that its cytoplasmic domain targets it to that location.[41,42] The extracellular domain of BPAG2 has been localized to anchoring filaments.[43] The autoantibodies from most patients with bullous pemphigoid (as well as those from patients with pemphigoid gestationis; see Chap. 57) recognize a particular epitope (called *NC16a*) in a small noncollagenous region of BPAG2 that is just outside the membrane.[44,45] As discussed in Pathophysiology of Lesion Production, antibodies against this epitope are capable of mediating sub-epidermal blister formation in neonatal mice. At initial presentation, enzyme-linked immunosorbent assay to measure reactivity of patient sera against the NC16a domain of BPAG2 is both sensitive and specific for a diagnosis of bullous pemphigoid.[46–48] In addition, antibody titers against this epitope, as determined by enzyme-linked immunoassay, correlate with disease activity.[49] Further evidence that BPAG2 mediates epidermal-dermal adhesion comes from analysis of the gene defect in patients with the genetic sub-epidermal blistering disease generalized atrophic benign epidermolysis bullosa. These patients have recessively inherited mutations in the *BPAG2* gene that result in a missing or dysfunctional protein (see Chap. 60).[50]

Not only patients with bullous pemphigoid and herpes gestationis but also patients with linear IgA disease, cicatricial pemphigoid, and lichen planus pemphigoides have antibodies against BPAG2 or its metabolic products.[51]

Pathophysiology of Lesion Production

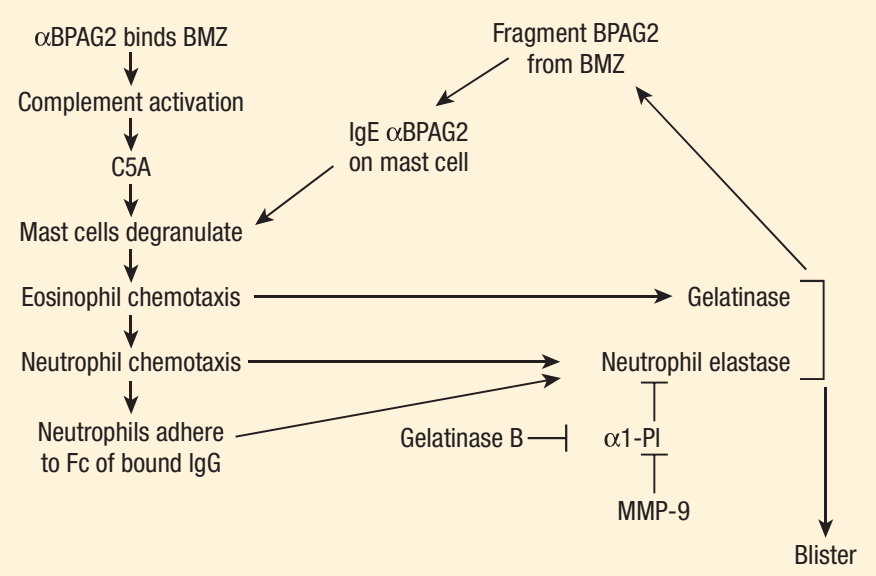
Autoantibodies, particularly those against BPAG2, detected in patients with bullous pemphigoid are probably pathogenic. Bullous pemphigoid IgG injected into rabbit cornea fixes to the basement membrane and causes subepithelial blister formation.[52] In vitro studies with normal human skin sections indicate that the bullous pemphigoid IgG is capable of activating complement by the classical pathway, thereby causing leu-

kocyte adherence to the basement membrane, with degranulation and resulting dermal-epidermal separation.[53] Almost all patients with active bullous pemphigoid have anti-BPAG2 IgG1, a subclass capable of complement fixation, whereas most patients in remission have anti-BPAG2 IgG4, which does not fix complement.[54]

In an elegant and informative animal model, it has been demonstrated that antibodies against BPAG2 can induce disease by passive transfer to neonatal mice.[55] In these studies, antibodies were raised in rabbits against the epitope on mouse BPAG2 that corresponds to the epitope that most human bullous pemphigoid and pemphigoid gestationis sera recognize. Passive transfer of these rabbit antibodies to neonatal mice induces blisters with histology very similar to that of bullous pemphigoid lesions. In this model, complement, neutrophils, and neutrophil elastase are necessary for anti-BPAG2 induction of blister formation.[56–59] Further observations with this model show that mast cell deficient, matrix metalloproteinase-9–deficient, and gelatinase B–deficient mice are resistant to anti-BPAG2 blistering.[60–63] Matrix metalloproteinase-9 and gelatinase B are thought to degrade antiproteinase 1 and decrease its inhibition of neutrophil elastase.[62,63]

IgE anti-BPAG2 antibodies may also play a role in blister formation.[17,18] The antibodies not only bind to the epidermal basement membrane, but also, through their Fc tail, bind the surface of mast cells. BPAG2 fragments, either released during the normal remodeling of the basement membrane or from protease degradation in bullous pemphigoid, or both, may bind these IgE antibodies, thereby causing degranulation of mast cells.

The preceding immunopathologic observations are consistent with a proposed pathophysiologic explanation for blister formation in bullous pemphigoid (Fig. 54-3).[63] The initial step in blister formation is postulated to be antibody binding to the bullous pemphigoid antigen. Fixation of IgG to the basement membrane activates the classic complement cascade and probably also the C3 amplification mechanism. Activated complement components cause chemotaxis of leukocytes as well as degranulation of mast cells. Anti-BPAG2 IgE may also contribute to mast cell degranulation. Mast cell products cause chemotaxis of eosinophils through mediators such as eosinophil chemotactic factor of anaphylaxis. Finally, leukocyte and mast cell proteases result in dermal-epidermal separation. For example, eosinophils, the predominant inflammatory cell at the basement membrane in bullous pemphigoid lesions, produce a gelatinase that cleaves the collagenous extracellular domain of BPAG2, probably contributing to blister formation.[64] In mice, neutrophil elastase is critical for blister formation, as discussed earlier in this section. Various other proteases may also be involved in regulating this cascade of events as shown in Fig. 54-3. The relative importance of each of these pathways in blister formation in humans remains to be determined.



▲ **FIGURE 54-3** Simplified schematic for one model of the pathophysiology of blister formation in bullous pemphigoid. BMZ, basement membrane zone; Ig = immunoglobulin; MMP-9 = matrix metalloproteinase 9.

In light of identification of the bullous pemphigoid antigens as components of the hemidesmosome, it also must be considered that antibodies may interfere directly with the function of this adhesion junction thought to be important in anchoring the basal cells to the basement membrane. In this regard, a mechanism of blister formation in which antibodies against BPAG2 interfere with hemidesmosome formation has been proposed.[65]

The involvement of antibodies against BPAG1, as opposed to BPAG2, in causing blisters is not as well established. A few experimental animal models suggest that these antibodies may be involved, especially after basement membrane damage, but the evidence not as convincing for primary causation as that for anti-BPAG 2 antbiodies.[66,67]

As in most autoimmune diseases, the cause of the induction of autoantibody production in bullous pemphigoid remains obscure, although the overexpression of the class II major histocompatability complex allele *DQbeta1*0301* in bullous pemphigoid patients suggests that presentation of BPAG2 peptides to the immune system in a way that causes disease is restricted to individuals with certain immune response genes.[68]

CLINICAL FINDINGS

Skin and Mucous Membrane Involvement

The skin lesion characteristic of bullous pemphigoid is a large, tense blister arising on normal skin or on an erythematous base (Fig. 54-4).[4] These lesions are most common on the lower abdomen, inner or anterior thighs, and flexor forearms, although they may occur anywhere. The bullae usually are filled with clear fluid but may be hemorrhagic. Eroded skin from ruptured blisters usually shows a good tendency to reepithelialize, and, unlike pemphigus vulgaris, these erosions do not tend to expand at the periphery. However, new, discrete vesicles may form at the edge of old, resolving lesions. The lesions of bullous pemphigoid do not scar. There is usually, but not always, marked pruritus.

Sometimes the erythematous component predominates, and patients may present with urticarial lesions, especially early in the course of disease (see Fig. 54-4B). The erythematous component also can appear serpiginous, with peripheral blisters, and may be quite ex-

▲ **FIGURE 54-4** Bullous pemphigoid. **A.** Large, tense bullae and erythematous macules on the thighs and lower legs. (Used with permission from James Fitzpatrick, MD.) **B.** Urticarial lesions of bullous pemphigoid.

tensive (Fig. 54-5). Resolution usually occurs from the center and may be accompanied by hyperpigmentation.

Mucous membrane lesions occur in approximately 10 percent to 35 percent of patients and are almost always limited to the oral mucous membranes, especially the buccal mucosa.[4,12] Intact blisters or, more usually, erosions are seen. These do not scar and usually are not extensive. Unlike erythema multiforme, the vermillion border of the lips is involved rarely.

In addition to the characteristic clinical findings, there have been descriptions of bullous pemphigoid with unusual presentations.[69] In all these cases, the diagnosis has been confirmed by immunofluorescence findings. For example, lesions in bullous pemphigoid sometimes are localized, most commonly to the lower legs.[70] These patients with localized disease have antibodies against the same pemphigoid antigens described in Pathophysiology of Lesion Production[71,72] and they may go on to generalized bullous pemphigoid or remain localized for years. There is a specific type of localized pemphigoid described in young girls in which blisters and erosions are limited to the vulvar and perivulvar area.[73] As in other forms of localized pemphigoid and childhood pemphigoid, antibodies from this disease bind the pemphigoid antigens.[6,73] Not infrequently, especially early in disease, patients may have only urticarial and eczematous lesions without bullae. Other less usual presentations include erythroderma, prurigo nodularis–like or vegetating lesions, and dyshidrotic dermatitis–like lesions. Again, the antibodies from these patients show typical immunofluorescence localization and bind the pemphigoid antigens.[74–77]

Precipitating Factors

Most cases of bullous pemphigoid occur sporadically without any obvious precipitating factors. However, there are several reports of precipitation of bullous pemphigoid by ultraviolet (UV) light, either UVB or psoralens with UVA, and radiation therapy.[78–81]

Laboratory Abnormalities

In addition to the immunopathologic features described earlier, almost one-half of patients will have elevated total serum IgE, levels of which are positively correlated with IgG anti–basement membrane zone immunofluorescence titers.[14,82,83] Furthermore, elevated levels of IgE correlate with the presence of pruritus.[14] Finally, approximately one-half of patients have peripheral blood eosinophilia, sometimes marked, but not correlated with serum IgE levels.[14,84]

HISTOPATHOLOGY

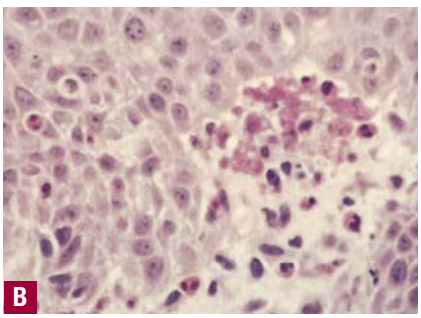
Biopsy of an early small blister is most diagnostic. Histology of such a biopsy shows a sub-epidermal blister without epidermal necrosis and with a superficial dermal infiltrate consisting characteristically of lymphocytes, histiocytes, and eosinophils (Fig. 54-6A).[4] The degree of the infiltrate ranges from intense to sparse, but it characteristically contains

▲ **FIGURE 54-5** Bullous pemphigoid. **A.** Extensive urticarial, inflammatory plaques with central regression and hyperpigmentation. **B.** Large, tense bullae and erythematous urticarial-type lesions.

some eosinophils. Biopsies from blisters arising on erythematous bases tend to have more extensive infiltrates. Eosinophils are also seen often in the blister cavity. Neutrophils may be seen in the infiltrate, but in contrast to histologic findings in dermatitis herpetiformis, they seldom form microabscesses in the papillary tips. Urticarial lesions may show only a superficial dermal infiltrate of lymphocytes, histiocytes, and eosinophils with papillary dermal edema. Histology of these urticarial lesions also may display degranulating eosinophils at the dermal-epidermal junction, with early separation of individual basal cells from the basement membrane and/or eosinophilic spongiosis (see Fig. 54-6B).[85]

ASSOCIATED DISEASES

There have been many case reports of bullous pemphigoid associated with malignancy. However, bullous pemphigoid occurs in elderly patients, as does malignancy, and case-control studies suggest that there is no increase, or a very small increase, in the incidence of malignancy in patients compared with age-matched controls.[86–88] However, there may be an increased incidence of malignancy in bullous pemphigoid patients



▶ **FIGURE 54-6** Histopathology of bullous pemphigoid. **A.** Sub-epidermal blister with an inflammatory cell infiltrate, containing eosinophils, in the superficial dermis. **B.** Degranulating eosinophils at the epidermal basement membrane and eosinophilic spongiosis.

with negative indirect immunofluorescence as compared with those with positive indirect immunofluorescence.[12,89] Whether this increase means that in indirect immunofluorescence–negative patients with bullous pemphigoid there is an overall increased incidence of malignancy compared with age-matched controls is not known. Most authors agree that, other than a general physical examination and good review of systems, an extensive screening workup for an asymptomatic malignancy is not indicated for a bullous pemphigoid patient.

The coexistence of bullous pemphigoid and lichen planus (see Chap. 26), referred to as *lichen planus pemphigoides*, has been well documented.[90] These cases show typical clinical, histologic, and immunopathologic features of both diseases. It is postulated that anti–basement membrane zone antibodies develop as a consequence of the damage induced by the T-cell lymphocytic infiltrate at the basement membrane in lichen planus. Some authors have reported an association of bullous pemphigoid with various other autoimmune diseases, including pemphigus.[91–94] These associations occur only rarely. Finally, there may be a slight increased incidence of psoriasis in bullous pemphigoid patients as compared with age-matched controls.[95,96]

DIFFERENTIAL DIAGNOSIS

Bullous pemphigoid can be differentiated easily from most other blistering diseases, such as linear IgA disease, chronic bullous disease of childhood, dermatitis herpetiformis, erythema multiforme, and pemphigus, by histology and immunofluorescence (Box 54-1). The most difficult diseases to differentiate from bullous pemphigoid are EBA and cicatricial pemphigoid.[97,98] EBA usually can be distinguished by clinical criteria if it presents as a noninflammatory mechanobullous disease (see Chap. 58). However, occasionally it may present as an inflammatory disease that may be similar clinically and histologically to bullous pemphigoid.[97] By routine direct and indirect immunofluorescence, these diseases also may show indistinguishable findings. However, EBA may be distinguished from bullous pemphigoid by indirect or direct immunofluorescence on skin incubated in 1 *M* sodium chloride to cause a split in the lamina lucida, as discussed in Immunopathology (see Fig. 54-2).[99] Immunoelectron microscopy also distinguishes these diseases because the IgG in EBA is below the lamina densa on the anchoring fibrils,[100] whereas the IgG in bullous pemphigoid is closely associated with the basal cell hemidesmosomes. Finally, autoantibodies from EBA patients bind type VII collagen.[101]

As opposed to bullous pemphigoid, cicatricial pemphigoid usually manifests clinical activity predominantly, if not exclusively, on mucous membranes (see Chap. 55). Cicatricial pemphigoid is characterized by desquamative gingivitis as well as inflammation and scarring of conjunctiva. If there is blistering of the skin, it may be transient or may result in scarring. Large, tense blisters, which are characteristic of bullous pemphigoid, are usually not seen in cicatricial pemphigoid.

Box 54-1

Differential Diagnosis of Bullous Pemphigoid

- Sub-epidermal blistering diseases with autoantibodies
  - Pemphigoid gestationis
  - Cicatricial pemphigoid
  - Epidermolysis bullosa acquisita
  - Linear immunoglobulin A disease and chronic bullous disease of childhood
  - Dermatitis herpetiformis
  - Bullous lupus erythematosus
  - Very rare diseases with not fully characterized basement membrane antigens (a, b)
- Sub-epidermal blistering diseases without autoantibodies
  - Erythema multiforme
  - Toxic epidermal necrolysis
  - Porphyria
  - Epidermolysis bullosa
- Intraepidermal blistering diseases with autoantibodies
  - Pemphigus
- Intraepidermal blistering diseases without autoantibodies
  - Allergic contact dermatitis (e.g., rhus dermatitis)
  - Bullous impetigo, staphylococcal scalded-skin syndrome
  - Friction blister
  - Hailey-Hailey disease
  - Incontinentia pigmenti

PROGNOSIS AND CLINICAL COURSE

Bullous pemphigoid, even without therapy, may be a self-limited disease, but it may last from several months to many years. Lever[4] reported that 8 of 30 adults with bullous pemphigoid, before the advent of glucocorticoid therapy, went into remission after approximately 15 months (range, 3 to 38 months) of active disease. The 1-year mortality of patients with bullous pemphigoid has been reported to be between 19 percent and 40 percent in Europe, but lower (less than 6 percent to 12 percent) in the United

States.[6,102–106] Old age and poor general health were associated with poor prognosis, as might be expected.[103] Thus, bullous pemphigoid is a potentially fatal disease mostly in the elderly, whose health already may be fragile.

Approximately one-half of treated patients go into remission within approximately 2.5 to 6.0 years; however, in individual patients, disease may continue for 10 years or more.[12,14] Clinical remission with reversion of direct and indirect immunofluorescence to negative has been noted in patients, even those with severe generalized disease, treated with oral corticosteroids alone or with azathioprine.[13,14]

TREATMENT

Localized bullous pemphigoid often can be treated successfully with topical corticosteroids alone (Box 54-2).[13,14,107] Topical tacrolimus has also been reported to be useful in a few cases of localized pemphigoid.[107–111]

More extensive disease, which may be more difficult to control than less extensive disease,[13] is usually treated with oral prednisone.[107,112] However, a randomized controlled clinical trial from France has shown that potent topical steroids are effective in both moderate and severe bullous pemphigoid, and in patients with extensive disease, but not moderate disease, topical therapy with 40 g/day of clobetasol propionate cream 0.05 percent, applied twice a day, was safer and more effective than oral prednisone starting at 1 mg/kg/day once a day.[113] This topical therapy did result in significant systemic absorption and may be effective through a combination of local and systemic effects.[114] Such therapy may not be practical in the United States.

In elderly patients, the complications of systemic glucocorticoid therapy (such as osteoporosis, diabetes, and immunosuppression) may be especially severe.[115] Therefore, it is important to try to minimize the total dose and duration of therapy with oral glucocorticoids. Starting doses of prednisone of 0.75 mg/kg/day or even less may be adequate for disease control.[116] In addition, immunosuppressive agents such as azathioprine (and less often methotrexate or cyclophosphamide) often are used for their potential steroid-sparing effects,[107,112,117–119] although very few controlled trials have addressed this common approach to therapy.[112,116] One of the few controlled trials for therapy of bullous pemphigoid found that if systemic corticosteroids are given at rather high dosage for 4 weeks without taper, the addition of azathioprine does not add appreciable benefit.[120] Therefore, the beneficial effects of azathioprine may reside in its steroid-sparing effects.[117] In elderly patients, these immunosuppressives may be used during initial therapy and even may be used without accompanying prednisone in limited disease. However, to bring widespread disease under rapid control, systemic or intensive topical corticosteroids are often necessary because their effect is usually rapid (within days), whereas immunosuppressives may take at least 4 to 6 weeks to show a salutary effect. High-dose "pulse" therapy with intravenous methylprednisolone also has been reported to be effective in rapidly controlling active blister formation in bullous pemphigoid.[121]

Sulfones may be effective in a minority of patients. Dapsone and sulfapyridine have been reported to control disease activity in 15 percent to 44 percent of bullous pemphigoid patients.[107,122–124]

Reports have described successful treatment of some bullous pemphigoid patients with tetracycline and nicotinamide or variations on this theme, such as erythromycin and nicotinamide or tetracycline alone.[125–127] In small numbers of patients, other therapies reported to be effective include mycophenolate mofetil (which may provide a less toxic alternative for azathioprine),[107,128,129] plasmapheresis,[130] intravenous γ globulin,[131–133] methotrexate,[134] leflunomide,[135] and chlorambucil.[136]

Box 54-2

Treatments for Bullous Pemphigoid

- Corticosteroids
  - High potency topical
  - Prednisone
- Other immunosuppressive agents
  - Azathioprine
  - Mycophenolate mofetil
- Modulators of antibody levels
  - Intravenous gammaglobulin
  - Plasmapheresis
- Other
  - Tetracycline or erythromycin and nicotinamide
  - Dapsone
  - Topical tacrolimus

CHAPTER 55

Cicatricial Pemphigoid

Kim B. Yancey

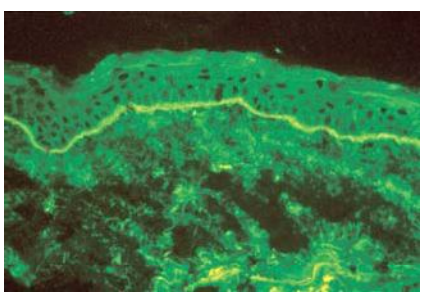
Cicatricial pemphigoid (alternate designation: mucous membrane pemphigoid) is a rare chronic autoimmune subepithelial blistering disease characterized by erosive lesions of mucous membranes and skin that result in scarring of at least some sites of involvement.[1–6]

EPIDEMIOLOGY

Cicatricial pemphigoid has been estimated to occur in approximately 1 person per million annually; females are affected 1.5 to 2.0 times as often as males.[7–9] Cicatricial pemphigoid has a mean age of onset of the early to middle 60s.[9] Although there is no known racial or geographic predilection, the *HLA-DQB1*0301* allele has been shown to be significantly increased in frequency in patients with oral, ocular, and generalized bullous pemphigoid; amino acid residues at positions 57 and 71 to 77 of the DQB1 protein may represent a disease susceptibility marker.[1,10–14]

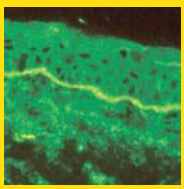
ETIOLOGY AND PATHOGENESIS

Autoantibodies directed against autoantigens in epidermal basement membrane are held responsible for the pathogenesis of cicatricial pemphigoid (Fig. 55-1). A variety of different autoantigens are recognized by circulating autoantibodies from these patients.[1,15–29] These and other findings have led to the idea that cicatricial pemphigoid is not a single nosologic entity but rather a disease phenotype. Autoantigens recognized by immunoglobulin G (IgG) autoantibodies from patients with cicatricial pemphigoid are summarized in Table 55-1. Bullous pemphigoid antigen 2 (BPAG2) appears to represent a major cicatricial pemphigoid autoantigen; other autoantigens of particular interest include laminin 5, integrin subunit β_4, integrin subunit α_6, type VII collagen, and bullous pemphigoid antigen 1. Other patients with cicatricial pemphigoid have IgA anti–basement membrane autoantibodies (alone or in conjunction with IgG anti–basement membrane autoantibodies); the best characterized IgA autoantigen linked to the cicatricial pemphigoid phenotype is bullous pemphigoid antigen 2.[1,30–32]



▲ **FIGURE 55-1** Direct immunofluorescence microscopy of normal-appearing perilesional skin from a patient with cicatricial pemphigoid shows continuous linear deposits of C3 in the epidermal basement membrane.

CICATRICIAL PEMPHIGOID AT A GLANCE



- A chronic autoimmune subepithelial blistering disease characterized by erosive lesions of mucous membranes and skin that result in scarring.
- Lesions commonly involve the oral and ocular mucosae; other sites that may be involved include the nasopharyngeal, laryngeal, esophageal, genital, and rectal mucosae.
- A rare disorder, occurring in 1 person per million annually; females are affected 1.5 to 2.0 times as often as males.
- A progressive disorder that may result in serious complications (e.g., blindness, loss of the airway, esophageal stricture formation).
- Immunopathologic studies of perilesional mucosa and skin demonstrate in situ deposits of immunoreactants in epithelial basement membranes; circulating anti–basement membrane autoantibodies are detected in sera of some but not all patients.
- A variety of different autoantigens are recognized by autoantibodies from patients, which suggests that cicatricial pemphigoid is not a single nosologic entity but rather a disease phenotype.

CLINICAL FINDINGS

History

Patients typically describe the onset of painful, erosive, and/or blistering lesions on one or more mucosal surfaces. A few skin lesions on the upper body are also sometimes noted. Associated symptoms are site specific as detailed later.

Mucosal and Cutaneous Lesions

The mouth is the most frequent site of involvement in patients with cicatricial pemphigoid; it is often the first (and only) site affected. Lesions often involve the gingiva, buccal mucosa, and palate (Figs. 55-2 and 55-3); other sites such as the alveolar ridge, tongue, and lips are also susceptible.[9,33] A frequent oral manifestation is desquamative gingivitis. Other lesions may present as tense blisters that rupture easily or as mucosal erosions that form as a consequence of epithelial fragility. Lesions in the mouth may result in a delicate white pattern of reticulated scarring. In severe disease, adhesions may develop between the buccal mucosa and the alveolar process, around the uvula and tonsillar fossae, and between the tongue and the floor of the mouth. Gingival involvement can result in tissue loss and dental complications (e.g., caries, periodontal ligament damage, and loss of bone mass and teeth).

Ocular involvement in patients with cicatricial pemphigoid is common and may become sight threatening (Fig. 55-4).[34,35] Ocular lesions typically manifest as conjunctivitis that progresses insidiously to scarring. Early ocular disease can be quite subtle and nonspecific. Although disease is usually bilateral, it often begins unilaterally and progresses to both eyes within several years. Patients may complain of burning, dryness, or a foreign-body sensation in one or both eyes; frank blisters on conjunctival surfaces are rarely seen. Early disease is best appreciated by slit-lamp examination. Because disease may be localized to the upper tarsal conjunctiva, it may escape detection without eversion of the eyelids. Chronic ocular involvement can result in scarring characterized by shortened fornices, symblepharons (i.e., fibrous tracts between bulbar and palpebral conjunctival surfaces), and, in severe disease, ankyloblepharons (i.e., fibrous tracts fusing the superior and

TABLE 55-1

inferior palpebral conjunctivae with obliteration of the conjunctival sac). Conjunctival scarring also can cause entropion and trichiasis (i.e., in-turning of the eyelashes) that result in corneal irritation, superficial punctate keratinopathy, corneal neovascularization, corneal ulceration, and/or blindness. Additional ocular complications include scarring of the lacrimal ducts, decreased tear secretion, and loss of mucosal goblet cells leading to decreased tear mucus content and unstable tear films. It is very important for patients with suspected ocular involvement to be examined by an ophthalmologist, because early disease may be subtle, is only identified by slit-lamp examination, and can result in severe complications. Cicatricial pemphigoid may be limited to the eyes.

Other sites that may be affected by cicatricial pemphigoid include the nasopharyngeal, laryngeal, esophageal, and anogenital regions. Nasopharyngeal lesions can result in discharge, epistaxis, excessive crust formation, impaired airflow, chronic sinusitis, scarring, and tissue loss. Laryngeal involvement may present as hoarseness, sore throat, or loss of phonation. Chronic laryngeal erosions, edema, and scarring may result in supraglottic stenosis and airway compromise that eventually necessitates tracheostomy.[36] Esophageal involvement may result in stricture formation, dysphagia, odynophagia, weight loss, and/or aspiration. Moreover, it has been suggested that esophageal dysfunction and gastroesophageal reflux may elicit or exacerbate laryngeal disease and/or bronchospasm in such patients. Although involvement of the genital and/or rectal mucosae in patients with cicatricial pemphigoid is rare, it can be a source of substantial pain and morbidity. Rare cases of urethral stricture, vaginal stenosis, and anal narrowing have developed as a consequence of this disease.

The skin is involved in 25 percent to 35 percent of patients with cicatricial pemphigoid. The most frequently affected areas are the scalp, head, neck, and upper trunk (Fig. 55-5). Lesions typically consist of small vesicles or bullae situated on erythematous and/or urticarial bases. Lesions rupture easily and are

often seen as small, crusted papules or plaques. The extent and number of cutaneous lesions are generally small; lesions sometimes recur in the same areas.

Related Physical Findings

SYSTEMIC ASSOCIATIONS A cohort of 35 patients with anti-epiligrin cicatricial pemphigoid was shown to have an increased relative risk for cancer.[37,38] Ten patients in this cohort had solitary solid cancers (three lung, three gastric, two colon, two endometrial); eight patients developed cancer after the onset of cicatricial pemphigoid (six within a year, seven within 14 months). The time between blister onset and cancer diagnosis was approximately 14 months in 9 of the 10 patients. Eight patients in this cohort died as a consequence of their cancer. All deaths occurred within 21 months. This form of cicatricial pemphigoid appears to have a relative risk for malignancy that approximates that for adults with dermatomyositis; as is true for the latter, the risk for cancer appears to be particularly high in the first year of disease. Other patients with anti-epiligrin cicatricial pemphigoid and cancer have been described more recently.[39–42]

BRUNSTING-PERRY PEMPHIGOID In 1957, Brunsting and Perry described seven patients with locally recurrent and scarring sub-epidermal blistering lesions of the head or neck that for many years was thought to be a form of cicatricial pemphigoid.[43] Although these patients are typically elderly and demonstrate deposits of immunoreactants in epidermal basement membranes like other patients with cicatricial pemphigoid, Brunsting-Perry pemphigoid predominates in men and lacks mucous membrane involvement. More recently, patients with the same clinical, histologic, and immunopathologic features have been reported to have autoantibodies directed against type VII collagen (or rarely to bullous pemphigoid antigens).[3,44] Identification of similar patients with blister planes beneath the lamina densa further suggests that individuals with this phenotype usually have localized forms of epidermolysis bullosa acquisita.

LABORATORY TESTS

Light Microscopy

Although the findings of light microscopy studies of lesional skin or mucosa from patients with cicatricial pemphigoid often are nonspecific, they characteristically show a sub-epidermal blister and a dermal leukocytic infiltrate composed of lymphocytes and histiocytes as well as variable numbers of neutrophils and eosinophils.[2,3,45] Plasma cells often are seen in mucosal lesions, whereas eosinophils and neutrophils are seen most commonly in skin lesions. Biopsy specimens of older lesions may be relatively "cell poor" and show features that correlate with the noninflammatory character of such sites clinically. Light microscopy studies of older lesions often show fibroblast proliferation and lamellar fibrosis (i.e., fibrosis characterized by collagen bundles ordered parallel to the surface epithelium).

Electron Microscopy

Ultrastructural studies of lesional skin or mucosa from patients with cicatricial pemphigoid show that blisters typically develop within the lamina lucida and eventuate in partial or complete destruction of the basal lamina in older lesions.[45–48] A generally held impression is that blisters form below those of bullous pemphigoid, because scarring is more common in patients with this disease. Reports of patients with blisters in the sublamina densa region are thought to represent mucosa-predominant forms of epidermolysis bullosa acquisita.

Immunofluorescence Microscopy

Direct immunofluorescence microscopy of normal-appearing perilesional tissue from patients with cicatricial pemphigoid shows continuous deposits of immunoreactants in epithelial basement membranes.[5,48] The most commonly detected immunoreactants are IgG and C3 (see Fig. 55-1); the predominant subclass of these autoantibodies is IgG4.[49] IgA, IgM, and/or fibrin are found in some patients.[50] One study of skin and mucosal samples from 10 patients found immunoreactants more commonly in perilesional mucosal biopsy specimens, which suggests that mucous membranes are the preferred biopsy site for direct immunofluorescence microscopy studies.[48] Splitting tissue samples with 1 *M* NaCl increases the sensitivity of direct immunofluorescence microscopy and facilitates identification of immunoreactants as well as their relative distribution within epithelial basement membranes.[51,52]

Indirect immunofluorescence microscopy studies using intact skin or mucosa often find low-titer IgG (and/or IgA) anti–basement membrane autoantibodies in patients with cicatricial pemphigoid.[1,3,5,53] The use of 1 *M* NaCl–split skin as a test substrate in these studies substantially increases the detection of such autoantibodies.[26,54,55] In such studies, IgG (and/or IgA) binding is usually directed against the epidermal side of 1 *M* NaCl–split skin, although combined epidermal and dermal or exclusively dermal binding can occur. In fact, this heterogeneity in autoantibody binding patterns was one of the first clues that cicatricial pemphigoid is a disease phenotype that is associated with different autoantigens (see Table 55-1). Although some studies have suggested that the use of human mucosal tissue substrates increases the likelihood of detecting autoantibodies in patients with cicatricial pemphigoid, other studies have not obtained similar results.[6,48] Patients with both IgG and IgA anti–basement membrane autoantibodies appear to have a worse prognosis as defined by requirements for medications to control disease as well as overall clinical severity score.[30,32]

Specialized Tests

Selected cases may require specialized immunochemical studies (e.g., immunoblot studies of keratinocyte or skin extracts, immunoprecipitation studies of biosynthetically radiolabeled keratinocytes) to identify the autoantigen targeted by patient anti–basement membrane autoantibodies. Perilesional tissue from seronegative patients may be further characterized by immunoelectron microscopy studies to determine if in situ deposits of immunoreactants reside above or below the lamina densa of epidermal basement membrane.

DIFFERENTIAL DIAGNOSIS

The diagnosis of cicatricial pemphigoid is suggested when patients present with bullous or erosive lesions of mucous membranes and continuous deposits of immunoreactants are demonstrated in epithelial basement membranes of perilesional tissue. Distinguishing cicatricial pemphigoid from other autoimmune bullous diseases can be difficult and may require specialized immunopathologic studies and/or immunoelectron microscopy. Disorders that must be differentiated from cicatricial pemphigoid include lichen planus, erythema multiforme, lupus erythematosus, lichen sclerosus, and—in the case of ocular disease—cicatrizing or inflammatory conjunctivitis that results from long-term use

Box 55-1

Differential Diagnosis of Cicatricial Pemphigoid

Most Likely

- Pemphigus
  - Pemphigus vulgaris
  - Paraneoplastic pemphigus
- Other sub-epidermal immunobullous diseases
  - Epidermolysis bullosa acquisita
  - Bullous pemphigoid
  - Linear immunoglobulin A dermatosis
- Erythema multiforme
- Lupus erythematosus
- Lichen planus

Consider

- Drug-induced hypersensitivity reaction
- Lichen sclerosus (especially in the anogenital area)

Always Rule Out

- Pemphigus (specifically, pemphigus vulgaris, paraneoplastic pemphigus)
- Other sub-epidermal immunobullous diseases
- Erythema multiforme
- Lupus erythematosus
- Lichen planus

of certain ophthalmologic preparations (e.g., pilocarpine, guanethidine, or ephedrine used in the treatment of glaucoma or idoxuridine used as an antiviral) or biologics that inhibit epidermal growth factor receptor tyrosine kinase (Box 55-1).[34,56] It also has been reported that some cases of ocular cicatricial pemphigoid develop after an acute episode of severe ocular inflammatory injury secondary to Stevens-Johnson syndrome[57] (see Chap. 39). Interestingly, the time between the appearance of Stevens-Johnson syndrome and the onset of ocular cicatricial pemphigoid in these patients can range from a few months to more than 30 years.

COMPLICATIONS

Site-specific complications of cicatricial pemphigoid were outlined earlier and are summarized in Table 55-2.

PROGNOSIS AND CLINICAL COURSE

Cicatricial pemphigoid is typically a chronic and progressive disorder, although involvement may be limited to a given anatomic site (e.g., the mouth, the conjunctivae) for many years. Cicatricial pemphigoid rarely goes into spontaneous remission; its treatment is largely determined by its severity and sites of involvement. Scarring can only be prevented in these patients; it cannot be completely reversed.

TABLE 55-2
Potential Complications of Cicatricial Pemphigoid

SITE	POTENTIAL COMPLICATIONS
Mouth	
Mucosa	Painful, erosive scarring lesions; adhesions between the buccal mucosa and the alveolar process; the uvula and the tonsillar fossae; the tongue and the floor of the mouth
Gingiva	Loss of gingival tissue, caries, periodontal ligament damage, loss of alveolar bone, loss of teeth
Eyes	
Conjunctivae	Painful, erosive conjunctivitis; foreign-body sensations; photophobia; scarring; shortened fornices; loss of goblet cells; decrease in tear mucus content, unstable tear film; symblepharons; ankyloblepharons
Eyelids	Ectropion, trichiasis, ankyloblepharons
Cornea	Corneal irritation, superficial punctate keratinopathy, corneal neovascularization, corneal ulcers, blindness
Tear ducts	Scarring, occlusion, secondary infection
Nose	Discharge, epistaxis, excessive crust formation, impaired airflow, recurrent and chronic sinusitis, scarring, tissue loss
Larynx	Hoarseness, impaired phonation, loss of voice, scarring, supraglottic stenosis, airway compromise and loss
Esophagus	Dysphagia, odynophagia, impaired swallowing, aspiration, stricture formation, weight loss
Anogenital region	Painful erosions, stenosis, stricture, secondary infection

TREATMENT

The following overview (Box 55-2) is representative of most treatment regimens.[4,58–60]

Mild lesions of the oral mucosa and skin can often be treated effectively with topical glucocorticoids (or calcineurin inhibitors such as tacrolimus) in a gel or ointment base applied two to four times each day.[59,61,62] These agents are particularly effective before bed, because oral secretions diminish during sleep. Because it is difficult to maintain contact of topical agents with mucous membranes (and because lesions often are localized to the gingiva), customized delivery trays to occlude topical glucocorticoids over lesional sites in the mouth are also useful.[63] This approach also facilitates interactions with professionals who can manage other complications in these patients (e.g., dental complications). Mouthwash (dexamethasone 100 µg/mL, 5 mL per rinse) used in a "swish-and-spit" regimen for 5 minutes two to three times each day represents another approach for topical therapy. For oral disease resistant to topical glucocorticoids, these agents can (in some instances) be administered intralesionally. In addition to these measures, patients should follow a strict regimen of oral hygiene that includes regular brushing, flossing, and cleaning of teeth. Use of toothpastes and mouthwashes that lack sodium lauryl sulfate and alcohol, respectively, often facilitates patient compliance with such activities.

A number of reports have suggested that dapsone (50 to 200 mg by mouth daily) may be effective.[35,64] Others have found that cicatricial pemphigoid does not respond to this agent. Systemic glucocorticoids can be administered alone (e.g., 20 to 60 mg of prednisone by mouth each morning) or in combination with dapsone. Because of potentially severe complications, ocular, laryngeal, and/or esophageal involvement requires aggressive management by teams of physicians familiar with specialized care of these organ systems. For mild or moderate ocular involvement, systemic glucocorticoids (e.g., 20 to 60 mg of prednisone by mouth each morning) alone or in conjunction with daily dapsone may be effective. Patients whose ocular disease is complicated by trichiasis may benefit from epilation, although this decision is best made by an ophthalmologist. For severe disease affecting the ocular, pharyngeal, or urogenital epithelia, a combination of systemic glucocorticoids and an additional immunosuppressive is indicated. In such cases, azathioprine (2.0 to 2.5 mg/kg/day), mycophenolate mofetil (1.0 to 2.5 g/day), or cyclophosphamide (1 to 2 mg/kg/day) are often used in conjunction with daily prednisone (1 mg/kg/day).[59,65–68] In this regimen, daily prednisone is tapered gradually over approxi-

Box 55-2

Treatments for Cicatricial Pemphigoid

MILD INVOLVEMENT

Sites	*Local Care Measures*
Mouth	Topical corticosteroid (gels or ointments) bid/qid; topical corticosteroids under occlusion (e.g., dental trays); topical calcineurin inhibitors; intralesional corticosteroids
Nose	Irrigation with isotonic saline bid/tid; nasal lubricants; topical corticosteroids (e.g., via sprays, inhalers)
Anogenital region	Topical corticosteroids; topical calcineurin inhibitors
Skin	Topical corticosteroids; topical calcineurin inhibitors

MODERATE INVOLVEMENT

Sites	*Therapeutic Options*
Mouth, eyes, nose, larynx, esophagus, anogenital region	Local care measures outlined above plus dapsone 50–200 mg daily, prednisone 20–60 mg each morning, or both of these agents simultaneously

SEVERE INVOLVEMENT

Sites	*Therapeutic Options*
Mouth, eyes, nose, larynx, esophagus, anogenital region	Local care measures outlined above plus prednisone (1 mg/kg each morning), intravenous immunoglobulin (2 g/kg body weight over 2–3 days every 2–6 wk for 4–6 mo), or both of these agents simultaneously in conjunction with azathioprine (2–2.5 mg/kg/day), mycophenolate mofetil (1–2.5 g/day), cyclophosphamide (1–2 mg/kg/day), or rituximab (375 mg/m^2 weekly × 4 then every 4–6 mo as needed)

mately 6 months, and the patient is maintained on the alternate agent alone for an additional 6 to 12 months. Such combined regimens have had success in halting the progression of severe ocular disease, limiting scarring, and producing long-term remissions. In an effort to avoid adverse effects and complications produced by prolonged treatment with immunosuppressive agents, some groups treat patients with intravenous immunoglobulin (i.e., intravenous immunoglobulin 2 g/kg of body weight administered over 2 to 3 days every 2 to 6 weeks for 4 to 6 months).[69–72] Another emerging trend in the management of patients with particularly severe disease is the use of biologic agents that antagonize tumor necrosis factor-α (e.g., etanercept, infliximab) or bind CD20 (rituximab).[73,74]

Involvement of the nasopharynx or esophagus potentially has severe complications and requires aggressive and specialized care. Nasal lesions often benefit from twice-daily irrigation of the nasal passages with saline or tap water as well as the use of topical emollients. Esophageal involvement requires medical management to avert dysphagia, pain, tissue loss, and secondary complications such as gastroesophageal dysfunction and reflux, stricture formation, aspiration, laryngeal irritation, or bronchospastic pulmonary disease. All patients with cicatricial pemphigoid require long-term follow-up because of the possibility for this chronic disease to relapse.

CHAPTER 56

Linear Immunoglobulin A Dermatosis and Chronic Bullous Disease of Childhood

Caroline L. Rao
Russell P. Hall III

Linear immunoglobulin A (IgA) dermatosis is a rare immune-mediated blistering skin disease that is defined by the presence of homogeneous linear deposits of IgA at the cutaneous basement membrane (Fig. 56-1). Although in the original description of patients with linear IgA dermatosis it was considered to be a manifestation of dermatitis herpetiformis (DH), it has now been clearly separated from DH on the basis of its immunopathology, immunogenetics, and lack of consistent association with a gluten-sensitive enteropathy.[1–4] Patients with linear IgA dermatosis can present with lesions suggestive of epidermolysis bullosa acquisita (EBA), DH, bullous pemphigoid (BP), lichen planus, or cicatricial pemphigoid.[1–5] These different clinical presentations appear to result from the IgA binding to different epidermal antigens.

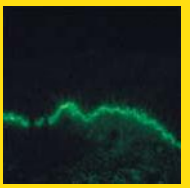
Chronic bullous disease of childhood (CBDC) is a rare blistering disease that occurs predominantly in children younger than 5 years of age and has an identical pattern of homogeneous linear IgA deposits at the epidermal basement membrane.[6,7] Recent studies have demonstrated that in some patients CBDC and linear IgA dermatosis represent different presentations of the same disease process.[8,9]

EPIDEMIOLOGY

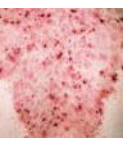
Linear IgA dermatosis occurs most often after puberty, with most patients presenting after the fourth decade of life.[2,10,11] A slight predominance of females has been noted in several studies.[2,10,11] In contrast, CBDC presents most often before the age of 5 years.[10] As in patients with linear IgA dermatosis, there is a slight female predominance in patients with CBDC.[7,10]

LINEAR IMMUNOGLOBULIN A DERMATOSIS

AT A GLANCE



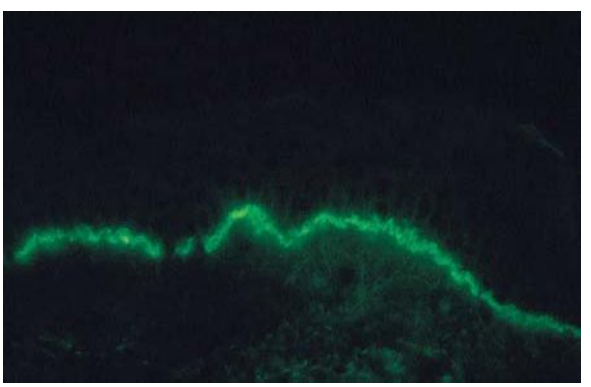
- Rare blistering disease with onset typically after fourth decade of life.
- Linear band of immunoglobulin A at the dermal epidermal basement membrane.
- Clinical presentations may mimic dermatitis herpetiformis, bullous pemphigoid, and cicatricial pemphigoid.
- May occur in association with many drugs, including vancomycin.
- May occur in association with inflammatory bowel disease but only rarely associated with gluten sensitive enteropathy.
- Rarely seen in association with malignancy, specifically lymphoid.
- Histology shows sub-epidermal collection of neutrophils at the basement membrane, often collecting in papillary tips with sub-epidermal blisters.
- Most patients respond dramatically to treatment with dapsone; some require adjunctive systemic corticosteroids.
- Prognosis variable with both spontaneous remissions and long-standing disease.



Evaluation of the HLA association in patients with linear IgA dermatosis and CBDC has yielded conflicting results. Some investigators have found an increased frequency of the human histocompatibility antigen HLA-B8 in patients with linear IgA dermatosis, whereas others have found no increased frequency.[12–14] In CBDC, an increased frequency of HLA-B8 has been noted, with up to 76 percent of patients expressing HLA-B8.[10] Collier et al. demonstrated an increased frequency of HLA-B8, -DR3, and -DQ2 in CBDC that was not seen in adults with linear IgA dermatosis.[12] These authors suggested that these haplotypes may have a role in earlier disease presentation. In addition, the *TNF2* allele was found with increased frequency in both adults and children with linear IgA disease when compared with unaffected subjects. There was, however, no increase seen in either adults or children when compared with HLA-DR3+ controls.

ETIOLOGY AND PATHOGENESIS: IMMUNOPATHOLOGY

Linear IgA dermatosis and CBDC are defined by the presence of a homogeneous linear band of IgA at the dermal-epidermal basement membrane zone. A minority of patients in both groups have additional deposits of other immunoreactants, most often IgG and occasionally the third component of complement (C3).[10] Because IgA is the predominant Ig of the secretory immune system, numerous investigators have attempted to determine if the IgA present in the skin of these patients is of mucosal origin. Characterization of the IgA subclass in the skin has revealed almost exclusively IgA1 and not the subclass most often associated with mucosa, IgA2.[15–17] In addition, neither secretory piece nor J chain, both of which are present in secretory IgA, have been found in the IgA present in the skin of patients with linear IgA deposits.[18]Although these data have led to suggestions that the IgA is not of mucosal origin, the true origin of the IgA deposits in the skin of these patients is not known.



◀ FIGURE 56-1 Direct immunofluorescence of normal-appearing perilesional skin from a patient with linear immunoglobulin A dermatosis. A homogeneous band of immunoglobulin A is present at the dermal-epidermal junction.

CHRONIC BULLOUS DISEASE OF CHILDHOOD

AT A GLANCE

- Rare blistering disorder of childhood presenting predominantly in children less than 5 years of age.
- Linear immunoglobulin A at the dermal epidermal basement membrane.
- Clinical presentation of tense bullae, often in perineum and perioral regions, giving a "cluster of jewels" appearance. New lesions sometimes appear around the periphery of previous lesions with a collarette of blisters.
- Histology shows sub-epidermal collection of neutrophils at the basement membrane, similar to linear immunoglobulin A bullous dermatosis.
- Most patients respond dramatically to treatment with dapsone.
- Spontaneous remissions, often within 2 years, are frequent.

Initially it was thought that patients with linear IgA dermatosis and CBDC rarely had circulating IgA antibodies against the epidermal basement membrane. Indirect immunofluorescence, using 1 *M* NaCl-split normal human skin as a substrate, demonstrates that the majority of patients with CBDC have low-titer circulating antibodies against the epidermal side of the split skin.[10,19] Circulating low-titer IgA antibodies directed against the epidermal basement membrane also have been found in adults with linear IgA dermatosis.[10,19] Others have reported binding of IgA antibodies from some patients to the dermal side of normal human split skin, suggesting that more than one antigen may be the target for the IgA anti–basement membrane antibodies.[19] Immunoelectron microscopic studies have been performed to determine the exact location of the IgA in the skin of patients with both linear IgA dermato-

sis and CBDC. Immunoelectron microscopy of the skin of patients with linear IgA deposits has revealed three distinct patterns of immunoreactants. In some patients with linear IgA dermatosis, the IgA deposits are found in the lamina lucida region of the basement membrane zone, similar to the location of immunoreactants present in the skin of patients with BP.[20,21] A second pattern of IgA deposition has been detected in which the IgA deposits are present at and below the lamina densa in a pattern similar to that seen in EBA.[20–22] Prost et al. have described a third pattern of immunoreactants in some patients with linear IgA dermatosis in which the IgA deposits are found both above and below the lamina densa.[21] In a similar manner, immunoelectron microscopic studies of skin of patients with CBDC have shown the IgA immunoreactants to be in either the lamina lucida or a sublamina densa location.[22,23] These findings further support the probability that multiple antigens may be involved as the targets in both adults and children with linear IgA deposits in the skin.

Although the relatively low titer of IgA antibodies against the basement membrane present in the sera of patients with both linear IgA dermatosis and CBDC has complicated the search for specific antigenic targets for the IgA, several investigators have made significant observations regarding the antigenic targets in these diseases. Zone et al.[24] studied sera from patients who had circulating IgA antibodies that bound to the epidermal side of 1 *M* NaCl-split normal human skin, as shown by indirect immunofluorescence. They found that serum IgA from patients with either CBDC or linear IgA dermatosis bound to a 97-kd protein. Immunoelectron microscopy revealed that the 97-kd antigen is present in the lamina lucida, below the hemidesmosome of normal human skin, in a location similar to where the IgA is localized in patients with CBDC and linear IgA dermatosis.[25] Subsequently, Zone et al. determined that the 97-kd linear IgA bullous disease antigen is identical to a portion of the extracellular domain of the 180-kd BP antigen (BPAG2 or collagen XVII), which is essential in anchoring basal keratinocytes to the epidermal basement membrane.[26] The BP antigen (BPAG2) consists of a 180-kd transmembrane protein and 120-kd portion that corresponds to the collagenous ectodomain. Roh et al. and Schumann et al. have reported that autoantibodies in patients with linear IgA dermatosis recognize the soluble 120-kd ectodomain of type XVII collagen[27,28] The 120-kd antigen target is not unique to linear IgA dermatosis because it is also the antigen targeted by autoantibodies in some patients with cicatricial pemphigoid and BP.[27,28] Furthermore, IgA antibodies and T cells from patients with linear IgA bullous dermatosis have been found to be directed against the NC-16A region of collagen type XVII, which is the same region against which the IgG and T cells from patients with BP are directed.[29,30] This may explain in part the overlap in clinical and histologic features of these conditions. Wojnarowska et al. have identified another possible target antigen in patients with linear IgA dermatosis and CBDC. Using sera from patients in whom the IgA bound to the epidermal side of 1 *M* NaCl-split skin on routine indirect immunofluorescence. They found that IgA in the sera of some patients with these diseases bound to a 285-kd protein (LAD 285) that was not the 230-kd BP antigen or type VII collagen, the EBA antigen.[31] Allen and Wojnarowska have analyzed the sera of over 70 patients with both linear IgA dermatosis and CBDC and found that the predominant antigenic target in these patients is the BP180 antigen (collagen XVII), but that some patients react with multiple antigens including the BP230, LAD 285, and other yet to be identified proteins.[32] In many patients, IgA appears to bind to several different antigenic targets, suggesting the possibility that there is epitope spreading. The clinical significance of these findings however, has not been established.[32]

CLINICAL FINDINGS

Cutaneous Manifestations

The clinical manifestations of linear IgA dermatosis are heterogeneous and often indistinguishable from those seen in patients with DH.[2,10,11,35] Patients may present with combinations of annular or grouped papules, vesicles, and bullae (Figs. 56-2 and 56-3). Typically, these lesions are distributed symmetrically on extensor surfaces, including elbows, knees, and buttocks. Lesions most often are very pruritic, resulting in numerous crusted papules (Fig. 56-4). The clinical presentation can be difficult to distinguish from that seen in patients with DH. However, the degree of pruritus seen in patients with linear IgA dermatosis is variable and, in general, less severe than that seen in patients with DH. Some patients with linear IgA dermatosis present with larger bullae, in a pattern more consistent with that seen in patients with BP, or occasionally with cutaneous findings similar to those seen in patients with EBA. Patients with drug-induced linear IgA bullous dermatosis have been reported with erythema multiforme–like findings and a toxic epidermal necrolysis–like presentation, with widespread bullae and mucosal involvement. Recovery has been reported with discontinuation of the offending agent alone, but these patients may benefit from dapsone therapy (see Treatment).[36–38]

The clinical presentation of CBDC is characterized most often by the development of tense bullae, often on an in-

▲ **FIGURE 56-2** Patient with linear immunoglobulin A dermatosis with crusted erosions, papules, and vesicles on the back and neck.

▲ **FIGURE 56-3** Patient with linear immunoglobulin A dermatosis with annular erythematous plaques on the thighs.

▲ **FIGURE 56-4** Patient with linear immunoglobulin A dermatosis with grouped urticarial papules on the back with scattered crusted erosions.

flammatory base.[6] These lesions occur most frequently in the perineum and perioral region and often may occur in clusters, giving a "cluster of jewels" appearance (Figs. 56-5, 56-6, and 56-7). New lesions sometimes appear around the periphery of previous lesions, with a resulting "collarette" of blisters. Patients often report significant pruritus and/or a burning of the skin with the development of skin lesions. Patients with CBDC often present with the acute development of large numbers of tense blisters, which may rupture and become secondarily infected.

Rarely, patients with linear IgA dermatosis may present with an acute febrile illness with arthritis, arthralgias, and generalized malaise.[39,40] The presence of multiple papules and vesicles in a patient with systemic signs and symptoms has led to the evaluation of these patients for systemic infections, including viral infections. Routine direct immunofluorescence, however, has revealed linear deposits of IgA, and these patients have responded to conventional therapy.

▲ **FIGURE 56-5** Patient with chronic bullous disease of childhood. Tense bullae and crusted papules are present on the abdomen, with a clustering of bullae noted in the perineal region.

▲ **FIGURE 56-6** Chronic bullous disease of childhood. Tense blisters on erythematous bases in the pubic and inguinal areas.

Mucosal Involvement

Mucosal involvement is an important clinical manifestation seen in patients with linear IgA dermatosis and CBDC. This involvement can range from largely asymptomatic oral ulcerations and erosions to severe oral disease alone as well as to severe conjunctival and oral disease typical of that seen in cicatricial pemphigoid.[10,41,42] Oral lesions may occur in up to 70 percent of patients with linear IgA disease.[10] Although most patients with linear IgA dermatosis and mucosal involvement have significant cutaneous disease, cases have been reported in the literature in which the presenting and predominant clinical manifestations are lesions of the mucous membranes.[42,43] These patients may present with desquamative gingivitis and oral lesions consistent with those seen in patients with cicatricial pemphigoid (see Chap. 54). Patients also may present with conjunctival disease and scar formation typical of that seen in patients with cicatricial pemphigoid (see Chap. 55). Patients with linear IgA bullous dermatosis have also been reported to present with severe laryngeal and pharyngeal involvement before the development of more typical cutaneous manifestitations.[44]

▲ **FIGURE 56-7** Extensive chronic bullous disease of childhood. Note tense and flaccid blisters without notable inflammation.

Disease Associations

The similar clinical presentation of many patients with linear IgA disease to that seen in patients with DH led to the investigation of patients with linear IgA disease for an associated gluten-sensitive enteropathy. Although some investigators have found evidence of minimal inflammatory changes in the small bowel of patients with linear IgA disease, numerous investigators have been unable to show that the majority of patients with linear IgA disease have significant evidence of the villous atrophy characteristically seen in patients with DH.[1,45] In addition, the clinical manifestations of linear IgA disease have not been controlled by the use of a gluten-free diet.[46] Circulating autoantibodies against tissue transglutaminase, which occur in high frequency in patients with untreated gluten-sensitive enteropathy and DH, have not been found in most patients with linear IgA diseases.[47]

Other conditions have been reported in association with linear IgA disease. One example is ulcerative colitis (UC), which can result in a clinical syndrome where the activity of both diseases is linked (i.e., as one disease flares, so does the other). Paige and co-workers reviewed 70 patients with linear IgA bullous dermatosis and found 7.1 percent had associated UC. The extent and reason for this association has yet to be established. Perhaps, the abnormal mucosal IgA1 production seen in patients with UC may play a role.[46,48,49] Baldari et al. reported a case of CBDC occurring after acute mononucleosis.[50] These authors suggest that this virus may have a role in initiation of the disease through immune stimulation. CBDC also has been reported in association with chronic granulomatous disease in the setting of *Paecilomyces* lung infection.[51] The relationship between these conditions and CBDC has yet to be established.

The relatively acute onset of clinical, histologic, and immunopathologic find-

ings consistent with linear IgA disease has been seen in patients who have been taking a variety of drugs, including vancomycin, lithium phenytoin, sulfamethoxazole/trimethroprin, furosemide, atorvastatin, captopril, and diclofenac.[36,38,52,53] Vancomycin is the most common drug that is associated with the development of linear IgA bullous dermatosis. The mechanism of this interaction is not known; however, a small number of patients with vancomycin-induced linear IgA disease have been reported to have circulating IgA antibodies directed against the BP180, BP230, and LAD 285 antigens.[54,55] In one case of vancomycin-induced linear IgA bullous dermatosis, rechallenge with vancomycin in a gradual manner did not result in a recurrence of the eruption.[56]

Linear IgA disease also has been associated rarely with a variety of malignancies. Patients with linear IgA disease have been reported with both lymphoid and nonlymphoid malignancies.[57,58] Godfrey et al. reported three cases of lymphoid malignancies in 70 patients with linear IgA disease followed for a mean of 8.5 years. This represented an increase over the predicted number of 0.2 cases in an age- and sex-matched population.[57] No increase in the rate of nonlymphoid malignancies was seen. These findings suggest a small risk of lymphoid malignancy in these patients. However, larger population-based studies need to be done to confirm these findings.

HISTOPATHOLOGY

Routine histopathology of an early lesion in patients with linear IgA dermatosis and CBDC reveals a sub-epidermal bulla with collections of neutrophils along the basement membrane, often accumulating at the papillary tips (Fig. 56-8). A mild lymphocytic infiltrate may be present around the superficial dermal blood vessels without any evidence of neutrophilic vasculitis. Occasionally, the inflammatory infiltrate is composed of eosinophils, but most frequently neutrophils are the major component of the sub-epidermal inflammation.[10,59,60] Electron microscopic examination of the blisters found in patients with both linear IgA dermatosis and CBDC has revealed that the blister forms either within the lamina lucida or in a sublamina densa location.[20,23] Most often the histopathology seen in linear IgA disease is difficult to distinguish from that seen in patients with DH. Smith et al.[60] reported that patients with linear IgA disease tended to have fewer papillary microabscesses and a more diffuse infiltrate of neutrophils at the basement membrane zone. However, Blenkinsopp et al. found no significant difference between the histopathology found in patients with linear IgA disease and those with DH.[59] In general, the histopathology of blisters in linear IgA disease, CBDC, and DH is virtually indistinguishable.

DIFFERENTIAL DIAGNOSIS

Linear IgA dermatosis often closely mimics the clinical pattern seen in patients with DH. Some patients may have findings that resemble those seen in patients with BP, cicatricial pemphigoid, EBA, and, rarely, toxic epidermal necrolysis. In a similar manner, patients with CBDC must be differentiated from those with DH of childhood and childhood BP. The findings of linear IgA deposits at the basement membrane by direct immunofluorescence, most often in the absence of IgG and the third component of complement, can distinguish this disease from BP, cicatricial pemphigoid, and EBA, whereas granular IgA deposits are found at the basement membrane in patients with DH (Box 56-1).

Box 56-1

Linear Immunoglobulin A Bullous Dermatosis Differential Diagnosis

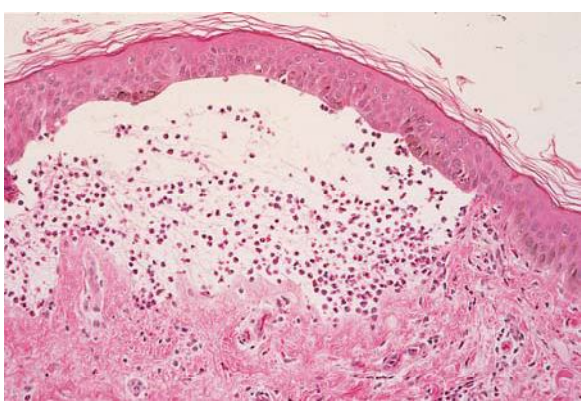
- Dermatitis herpetiformis
- Bullous pemphigoid
- Epidermolysis bullosa acquisita
- Bullous eruption of systemic lupus erythematosus
- Cicatricial pemphigoid
- Lichen planus
- Toxic epidermal necrolysis

TREATMENT AND PROGNOSIS

Adults with linear IgA dermatosis have an unpredictable course.[2,10] Many patients have disease that continues for years, with few, if any, episodes of remission. Occasionally, patients may have a spontaneous remission with loss of clinical features of the disease and disappearance of the linear IgA deposits in the skin. Patients with severe mucosal disease, especially of the eyes, may have persistent problems with symblepharon formation and resulting structural problems with the eyelids and cornea, even after active blistering has remitted.

Patients with linear IgA disease most often respond dramatically to dapsone or sulfapyridine. This response usually occurs within 24 to 48 hours, in a manner similar to that seen with DH; as such, it is not a helpful diagnostic sign for linear IgA disease.[2,10,11] Although most patients are well controlled with dapsone or sulfapyridine alone, some patients require low-dose prednisone therapy to suppress blister formation.[9,10] The majority of patients with linear IgA disease cannot control their skin disease with a gluten-free diet.[42]

CBDC is most often a self-limited disease, with most children going into remission within 2 years of the onset of the disease.[6,7,10] Occasionally, the disease persists well into puberty but often is less severe than the initial eruption. Patients with CBDC respond in a similar dramatic fashion to dapsone or sulfapyridine.[6,7,10] Many children, however, require the addition of relatively small doses of prednisone to bring the disease under control.[6,7] Mycophenolate mofetil has been used as a steroid-sparing agent in isolated cases.[61] Intravenous immunoglobulins have also been proposed in the rare patient not responding to, or intolerant of, dapsone therapy.[62,63] Several case reports suggest that some patients with CBDC may respond to antibiotics, including sulfonamides, dicloxacillin, and erythromycin.[64, 65] In a recent case series, seven children with linear IgA disease treated with flucloxacillin demonstrated im-



◀ **FIGURE 56-8** Histopathology of lesional skin from a patient with linear immunoglobulin A dermatosis showing a subepidermal blister filled with neutrophils. (Used with permission from Kim B. Yancey, MD.)

provement, with four achieving remission within 3 months.[66] However, spontaneous remission in these patients cannot be ruled out.

CHAPTER 57

Pemphigoid Gestationis (Herpes Gestationis)

Jeff K. Shornick

EPIDEMIOLOGY

Pemphigoid gestationis (PG) is the least common, yet best-characterized, dermatitis specific to pregnancy.[1] It classically presents as an intensely itchy, urticarial rash during the later part of pregnancy or the immediate postpartum period, then rapidly progresses to a pemphigoid-like, vesiculo-bullous eruption. The rash may wax and wane during pregnancy, only to flare during labor and delivery. PG appears to be mediated by a specific immunoglobulin G (IgG) directed against the cutaneous basement membrane zone (BMZ).

PG occurs in approximately 1 in 50,000 pregnancies.[2,3] It is associated with HLA-DR3 and DR4, and it appears likely that the incidence in various ethnic groups parallels the frequency of these genes in different populations.[4]

ETIOLOGY AND PATHOGENESIS

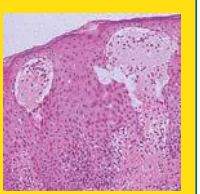
PG appears to be caused by an anti-BMZ antibody that induces C3 deposition along the dermal-epidermal junction. The PG autoantibody is an IgG that is infrequently found by direct immunofluorescence (IF), although indirect, complement-added IF reveals the circulating IgG in the majority of patients. In salt-split skin, staining remains with the epidermal fragment. An enzyme-linked immunosorbent assay (ELISA) for the PG antibody is now commercially available, and when this highly sensitive test is used, antibody titers appear to correlate with disease activity.[5] The PG autoantibody belongs to the IgG1 subclass and fixes complement via the classical complement pathway.[6] T cells also show selective NC16A reactivity in PG, although their role in disease development remains to be elucidated.[7]

Nearly all patients with PG [and most patients with bullous pemphigoid (BP)] have demonstrable antibodies to BP180 (type XVII collagen), a 180-kd transmembrane protein with its N-terminal end embedded within the intracellular component of the hemidesmosome and its C-terminal end located extracellularly (see Chap. 51). The extracellular section contains a series of 15 collagenous components alternating with 16 short, non-collagenous domains. The sixteenth non-collagenous segment closest to the plasma membrane of the basal keratinocyte is designated NC16A and contains the immunoreactive site.[8,9] The PG autoantibody is assumed to be pathogenic for several reasons: (1) It is found in essentially all patients. (2) In vitro, purified antibodies to BP180 from patients with BP cause chemoattraction to the dermal-epidermal junction with subsequent degranulation and dermal-epidermal separation.[10] (3) Rabbit antibodies to BP180 in animal models induce sub-epidermal blisters when infused into neonatal mice or hamsters.[11,12]

The BP180 protein differs significantly from the BP230 protein recognized by the majority of BP sera.[13,14] The 230-kd protein is coded for on the short arm of chromosome 6.[15] Its complementary DNA (cDNA) has been sequenced[16] and codes for an intracellular protein[17] that shows considerable homology with desmoplakin I.[18] The 180-kd protein is coded for on the long arm of chromosome 10.[19] Its cDNA shows no homology with the 230-kd cDNA but rather encodes a protein with two domains showing the primary structure of tri-helical collagen.[20]

What initiates the production of autoantibody remains unclear, but because gestational pemphigoid is exclusively a disease of pregnancy, attention has fo-

PEMPHIGOID GESTATIONIS AT A GLANCE



- Acute-onset, intensely pruritic, vesiculobullous eruption of pregnancy or the immediate postpartum period.
- Rare, occurring in roughly 1 in 50,000 pregnancies.
- Histopathology: dermal-epidermal separation with numerous eosinophils.
- Direct immunofluorescence: linear deposition of C3, with or without immunoglobulin G, along the basement membrane zone of the epidermal fragment of salt-split skin.
- Enzyme-linked immunosorbent assay for pemphigoid gestationis antibody (BP180) commercially available.
- No significant maternal morbidity or mortality.
- Associated with a slight increase in premature and small-for-gestational-age births.

cused on immunogenetics and potential cross-reactivity between placental tissue and skin.

Immunogenetic studies reveal an increase in HLA antigens DR3 or DR4, and curiously, nearly 50 percent of patients have the simultaneous presence of both.[21] The extended haplotype HLA-A1, B8, DR3 is known to be in linkage disequilibrium with a deletion of C4A (the C4 null allele or C4QO). Indeed, 90 percent of patients have either a C4AQO or a C4BQO.[22] Whether the C4QO association is the primary genetic marker for PG or whether the presence of a C4QO is even clinically relevant to complement function, however, remains to be shown.

It is worth noting that patients with neither DR3 nor DR4 may have clinically indistinguishable disease; the presence of the characteristic HLA antigens alone is not sufficient to produce disease.[21]

Essentially, 100 percent of women with a history of PG have demonstrable anti-HLA antibodies.[23,24] Because the only source of disparate HLA antigens is typically the placenta (which is primarily of paternal origin), the universal finding of anti-HLA antibodies implies a high frequency of immunologic insult during gestation. Indeed, a slight increase in HLA-DR2 in the husbands of women with PG has been reported.[23] It has been suggested that immunologically primed women may simply react more strongly to tissue with disparate HLA antigens. Whether anti-HLA antibodies represent phenomenon or epiphenomenon, remains to be clarified.

The autoantibody of gestational pemphigoid binds to amniotic basement membrane, a structure derived from fetal ectoderm and antigenically similar to skin.[25,26] Women with PG also show an increased expression of major histocompatibility complex class II antigens (DR, DP, DQ) within the villous stroma of chorionic villi but not skin.[27,28] It has therefore been proposed that PG is a disease initiated by the aberrant expression of major histocompatibility complex class II antigens (of paternal haplotype) within the placenta that serves to initiate an allogeneic response to placental BMZ, which then cross-reacts with skin.[29]

On the other hand, PG has also been reported in association with hydatidiform moles[30] and choriocarcinomas.[31] This is an intriguing clinical observation, because most hydatidiform moles are produced by a diploid contribution of paternal chromosomes and contain neither fetal tissue nor amnion. There are no case reports of a PG-like rash in males with choriocarcinoma. Unlike its counterpart in women, choriocarcinoma in males is strictly syngeneic tissue. Because choriocarcinoma in women is entirely derived from placental tissue (which is largely of paternal derivation), the suggestion is that the development of PG is somehow dependent on the state of partial allograph, not necessarily on the presence of amnion.

CLINICAL FINDINGS

PG is exclusively associated with pregnancy. It typically presents during late pregnancy with the abrupt onset of intensely pruritic urticarial lesions. Fifty percent of patients experience first onset on the abdomen, often within or immediately adjacent to the umbilicus. The other half present with typical lesions, but in an atypical distribution (extremities, palms, or soles). Rapid progression to a generalized, pemphigoid-like eruption, sparing only the face, mucous membranes, palms, and soles is the rule (although any site may be involved). Flares occur with delivery in approximately 75 percent of patients and may be dramatic. The explosive onset of blistering may occur within hours of delivery, either as a flare of pre-existing disease or as presentation de novo. Up to one-quarter of patients initially present during the immediate postpartum period.

Newborns may be affected up to 10 percent of the time, but the disease is typically mild and self-limited. IF of newborn skin may yield positive findings despite a lack of clinically apparent disease, which suggests that more than C3 deposition alone is required to induce lesions.[32]

Because of clinical and IF similarities with BP, and because of the considerable confusion over the term *herpes gestationis* (particularly outside dermatology), most authors have accepted the revised terminology of PG.[33] However, there are several differences worth bearing in mind: (1) BP is a disease of the elderly and shows no gender bias. PG is exclusively associated with pregnancy. (2) PG shows a strong association with HLA-DR3, -DR4, and a C4 null allele. BP does not. (3) Indirect IF in BP yields positive results in the majority of patients, and the titer of anti-BMZ antibody is often high. The titer of anti-BMZ antibody in PG is usually so low that antibody cannot be detected without the use of complement-added or ELISA techniques. (4) The majority of BP sera react to an intracellular 230- to 240-kd component of the hemidesmosome. Sera from most PG patients react to a 180-kd transmembrane protein with a collagenous domain coded for on a different chromosome. Until such time as nosology is driven by pathologic mechanism instead of clinical observation, naming is likely to remain fungible.

▲ **FIGURE 57-1** Pemphigoid gestationis. Polymorphic lesions on dorsa of feet.

Cutaneous Lesions

The typical lesions of PG are urticarial or arcuate plaques that rapidly progress toward a mixed dermatitis, including tense, pemphigoid-like blisters (Figs. 57-1, 57-2, and 57-3). Blisters may arise within urticarial plaques or on otherwise normal-appearing skin. Pruritic urticarial papules and plaques of pregnancy (see Chap. 107) can show microvesiculation but not the tense, sub-epidermal blisters of PG.

Related Physical Findings

PG is seen exclusively in women and only in the presence of pregnancy (or trophoblastic tissue). Any other setting is inconsistent with this diagnosis.

LABORATORY TESTS

Results of routine laboratory investigations are normal. Histopathology classically reveals a sub-epidermal vesicle with a perivascular infiltrate of lymphocytes and eosinophils (Fig. 57-4). Eosinophils may be lined up along the dermal-epidermal junction and typically fill the vesicular space. Classic findings, however, are seen only in the minority of cases. A nonspecific mixed cellular infiltrate containing a variable number of

▲ **FIGURE 57-2** Pemphigoid gestationis. Erythematous urticarial and bullous lesions on the chest and shoulders.

eosinophils is more common. The presence of eosinophils is the most constant feature of PG.

Special Tests

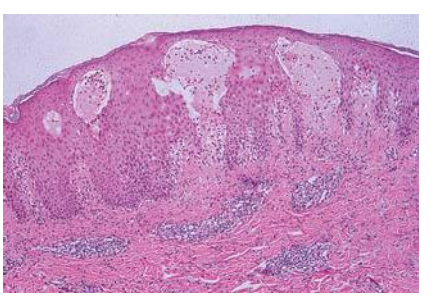
The sine qua non for a diagnosis of PG is the finding of C3, with or without IgG, in a linear band along the BMZ of perilesional skin (Fig. 57-5). In salt-split skin specimens, antibody deposition is found along the bottom of the epidermal fragment, a finding similar to that seen in BP. Indirect IF only occasionally detects circulating IgG deposition. However, complement-added indirect IF reveals the circulating anti-BMZ IgG in nearly all patients. The PG ELISA now available will likely replace IF.

▲ **FIGURE 57-3** Pemphigoid gestationis. Urticarial papules and plaques on the trunk.

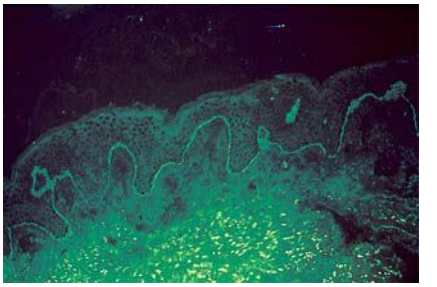
Anti-BMZ antibody titers correlate with the extent and severity of disease, but only if ELISA tests are used.[5] There is no apparent correlation between HLA type and clinical activity.[21] An increased incidence of antithyroid antibodies has been documented, but clinically apparent thyroid dysfunction appears rare.[34] Antinuclear antibodies are not seen, and serum complement levels are normal.

DIFFERENTIAL DIAGNOSIS

Since early lesions of PG can be urticarial, the most frequent frustration is differentiating PG from pruritic urticarial papules and plaques of pregnancy, otherwise known as *polymorphous eruption of pregnancy* (see Chap. 107). PG usually progresses rapidly, which makes the clinical diagnosis apparent. Allergic contact dermatitis and drug eruptions might also be difficult to distinguish. Where doubt exists, IF (or ELISA) is the key to differentiation and is particularly relevant in helping patients plan for future pregnancies (Fig. 57-6 and Box 57-1).



▲ **FIGURE 57-4** Pemphigoid gestationis. Subepidermal vesicle formation; dermal edema; infiltrate consisting of lymphocytes, histiocytes, eosinophils, and a few neutrophils; and focal basal cell necrosis. Note bulbous, teardrop-like vesicles.



▲ **FIGURE 57-5** Pemphigoid gestationis. Linear deposition of C3 along the basement membrane zone.

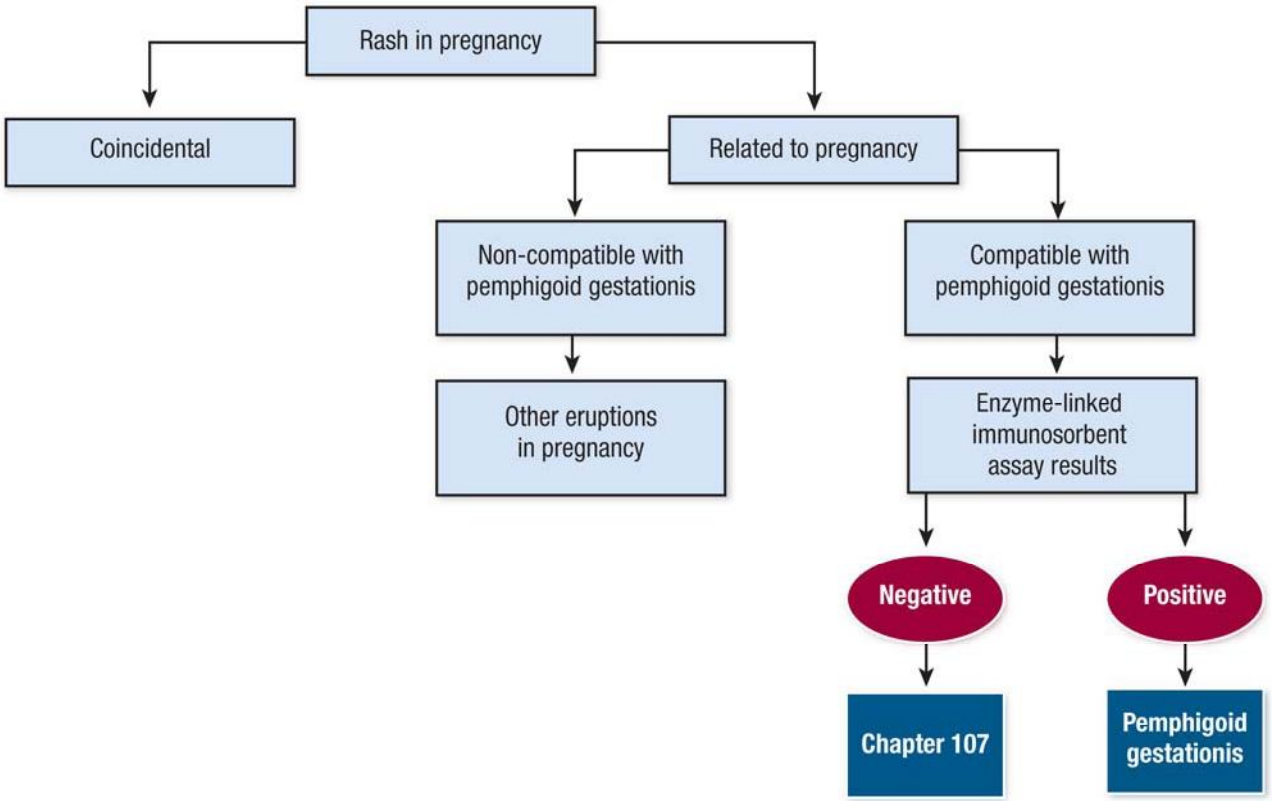
COMPLICATIONS

No increase in maternal morbidity or mortality has been documented, although the impression of such an increase remains from a review of individual case reports. Cutaneous disease in the newborn is typically self-limited and rarely requires intervention. Although there is an increased risk of premature and small-for-gestational-age births,[32] there are no data to suggest that treatment with systemic corticosteroids alters the risk of premature delivery. That being the case, it is imperative that the risks of therapy be balanced against the severity of the symptoms.

Women with a history of PG appear to be at increased risk for the subsequent development of Graves disease.[34]

PROGNOSIS AND CLINICAL COURSE

The clinical presentation and course of disease may be extremely variable. Many patients experience spontaneous resolution during the later part of gestation only to experience a flare, sometimes dramatically, at the time of delivery. Others develop relatively trivial urticarial lesions during one pregnancy, only to suffer characteristic blistering during a subsequent gestation. Still others develop classic disease during one pregnancy, then no disease during the next. The frequency of such "skip pregnancies" approximates 5 percent to 10 percent.[35] Recurrences associated with menstruation are common, and flares during the subsequent use of oral contraceptives occur in at least 25 percent of patients.



▲ **FIGURE 57-6** Approach to the patient with pemphigoid gestationis.

Most disease spontaneously remits over weeks to months following delivery, although there are isolated reports of protracted postpartum involvement. It has often been said that once gestational pemphigoid develops, it tends to occur earlier and with greater severity during subsequent gestations, but there are no data to support this contention.

No clear pattern of paternal contribution, if there is one, has yet been elucidated. First onset during both primiparous and multiparous pregnancies has been reported, with and without a change in partners.

Box 57-1

Differential Diagnosis of Pemphigoid Gestationis

Most Likely

- Urticarial pemphigoid gestationis
- Pruritic urticarial papules and plaques of pregnancy
- Other eruptions of pregnancy (see Chap. 107)
- Contact dermatitis
- Drug eruption

Consider

- Urticaria
- Erythema multiforme
- Dermatitis herpetiformis

Rule Out

- Pemphigus vulgaris
- Varicella

TREATMENT

Gestational pemphigoid is sufficiently rare that no controlled studies are available. Nonetheless, there is general consensus that treatment with topical corticosteroids and antihistamines is ineffective. Systemic corticosteroids remain the cornerstone of therapy. Most patients respond to 0.5 mg/kg of prednisone (prednisolone) daily. Maintenance therapy, generally at a lower dosage, may or may not be required throughout gestation. As noted earlier, many patients experience spontaneous disease regression during the third trimester, only to experience flare during parturition.

In individual cases, alternatives to corticosteroids (dapsone, pyridoxine, cyclosporine) or adjuvants (gold, methotrexate, cyclophosphamide, plasmapheresis) have been tried. None, with the possible exception of cyclosporine, is useful prior to term, and the experience with each has been variable at best. There are obvious concerns with the use of any of these alternatives during pregnancy.

PREVENTION

Only a small percentage of women who express DR3, DR4, or the combination of DR3 and DR4 ever develop PG, and the role of the paternal tissue in the development of disease (if any) is far from clear. With no predictive test available, prevention is not possible.

Those with a history of PG face the likelihood (but not the assurance) of recurrent involvement during subsequent gestations and are likely to develop symptoms during the use of oral contraceptives. Women who have experienced PG need not avoid additional pregnancies. They should, however, be counseled that recurrent disease is the rule.

CHAPTER 58

Epidermolysis Bullosa Acquisita

David T. Woodley
Mei Chen

EPIDEMIOLOGY

Epidermolysis bullosa acquisita (EBA) is a sporadic autoimmune bullous disease of unknown etiology and with no gender, ethnic, or geographic predisposition. Although EBA does not have a Mendelian pattern type of inheritance, there may be some genetic predisposition to EBA and autoimmunity in African Americans who live in the southeastern part of the United States.[1] African American patients in the southeastern part of the United States who have either EBA or bullous systemic lupus erythematosus (SLE) have a high incidence of the HLA-DR2 phenotype. The calculated relative risk for EBA in HLA-DR2+ individuals is 13.1 in these patients. These results also suggest that EBA and bullous SLE are immunogenetically related and that either the HLA-DR2 gene is involved with autoimmunity to anchoring fibril collagen or is some sort of a marker for some other gene that exists in linkage disequilibrium with it.[1]

ETIOLOGY AND PATHOGENESIS

EBA is a chronic, sub-epidermal blistering disease associated with autoimmunity to the collagen (type VII collagen) within anchoring fibril structures that are located at the dermal-epidermal junction (DEJ). Although the precise etiology of EBA is unknown, most of the evidence suggests an autoimmune etiology. The immunoglobulin G (IgG) autoantibodies to type VII collagen are associated with a paucity of normal anchoring fibrils at the basement membrane zone (BMZ) separating the epidermis from the dermis and poor epidermal-dermal adherence. Although it is an acquired disease that usually begins in adulthood, it was placed in the category epidermolysis bullosa (EB) approximately 100 years ago because physicians were struck by how similar the clinical lesions of EBA were to those seen in children with hereditary dystrophic forms of EB. Direct immunofluorescence (DIF) of perilesional skin biopsies from EBA patients reveals IgG deposits at the DEJ.[2] EBA antibodies bind to type VII collagen within anchoring fibrils (see Chap. 51).[3,4]

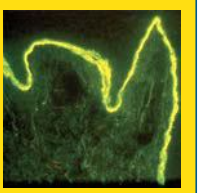
Anchoring fibrils anchor the epidermis and its underlying BMZ to the papillary dermis. Patients with hereditary forms of dystrophic EB (see Chap. 60) and EBA have decreased numbers of anchoring fibrils in their DEJ. This paucity of anchoring fibrils is associated with two similar clinical phenotypes, EBA and dystrophic forms of hereditary EB, because both diseases are characterized by skin fragility, sub-epidermal blisters, milia formation, and scarring. Although both EBA and hereditary forms of dystrophic EB are etiologically unrelated in terms of their underlying pathogenesis, they share the common feature of decreased anchoring fibrils. In the case of dystrophic forms of hereditary EB, the cause of decreased or absent anchoring fibrils is a genetic defect in the gene that encodes for type VII collagen α chains that ultimately results in small, nonfunctional or decreased anchoring fibrils.[5,6] The gene coding for type VII collagen is located on the short arm of chromosome 3, approximately 21 cm from zero.[7] The gene defects involved in hereditary forms of dystrophic EB have been identified at variable locations, but the severity of the disease appears to correlate with the degree of type VII collagen and anchoring fibril perturbations.[6] In EBA, the IgG autoantibodies binding to the type VII collagen α chains result in decreased anchoring fibrils, but the pathway leading to this reduction is unknown. It may be that type VII collagen α chains that are newly synthesized but decorated with EBA autoantibodies cannot form triple-helical structures and stable anchoring fibrils. Healed burn wounds that have been covered with cultured keratinocyte sheets also have decreased numbers of anchoring fibrils within the first year after transplantation, and this is associated with spontaneous blister formation, shortened suction blistering times, and skin fragility.[8] These observations provide indirect evidence that anchoring fibrils play a role in maintaining adherence between the epidermis and dermis.

The type VII collagen α chain has a molecular mass between 250 and 320 kd, and the collagen consists of a homotrimer of three identical α chains (see Chap. 51). Each α chain consists of a large globular noncollagenous amino terminus called the *non-collagenous 1* (NC-1) *domain* that is approximately one-half the entire mass of the α chain. Next, there is a helical domain with typical glycine-X-Y repeats. At the carboxyl terminus is a second globular noncollagenous domain, NC-2, that is much smaller than NC-1.[9] Most EBA autoantibodies recognize four predominant antigenic epitopes within the NC-1 domain and do not recognize the helical or NC-2 domains.[10,11] There may be something intrinsically "antigenic" about the NC-1 domain because the available monoclonal antibodies that have been generated against type VII collagen (anti–C-VII antibodies) specifically recognize only NC-1 subdomains.

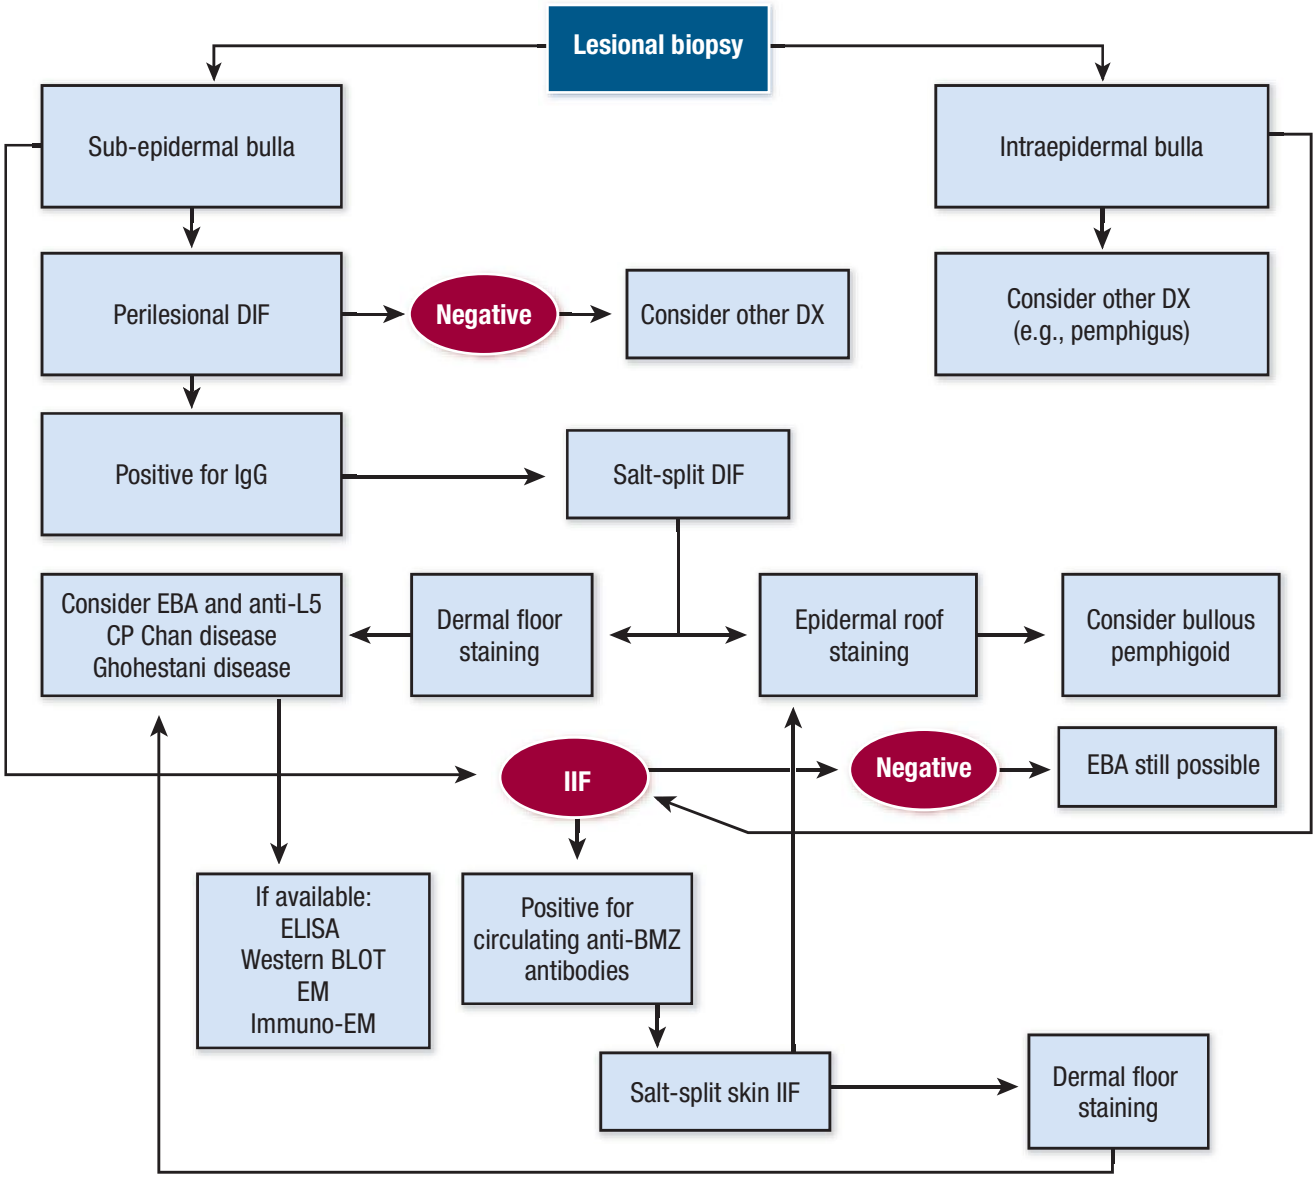
A reduction in the number of anchoring fibrils is seen in lesional and perilesional skin of EBA patients, but the pathway leading to this reduction is unknown.

Several independent lines of evidence have implicated autoimmune responses

EPIDERMOLYSIS BULLOSA ACQUISITA AT A GLANCE



- Rare, autoimmune sub-epidermal bullous disease due to immunoglobulin G autoantibodies to type VII collagen.
- Etiology is unknown.
- Skin fragility, sub-epidermal blisters, residual scarring, and milia formation. Common sites are trauma-prone areas such as hands, feet, elbows, knees, sacrum, nails, and mouth.
- Related features may include an underlying systemic disease such as inflammatory bowel disease. May have erosions of the mucosa and esophageal stenosis.
- Pathology shows sub-epidermal bulla, fibrosis, milia formation, and positive direct immunofluorescence for immunoglobulin G deposits at the epidermal-dermal junction.
- Treatment options limited and often difficult.



▲ **FIGURE 58-1** Approach to the patient with epidermolysis bullosa acquisita (EBA). BMZ = basement membrane zone; DIF = direct immunofluorescence; DX = diagnosis; ELISA = enzyme-linked immunosorbent assay; IgG = immunoglobulin G; IIF = indirect immunofluorescence.

as a key element in the pathogenesis of EBA. First, the pathogenic role of EBA antibodies is suggested by the observation that when patients with SLE develop autoantibodies to the EBA antigen, they develop widespread skin blisters and fall into a subset of SLE called *bullous SLE*.[16] This "experiment of nature" suggests that EBA autoantibodies are pathogenic and capable of inducing disadherence between the epidermis and dermis. Secondly, direct proof that EBA autoantibodies are pathogenic comes from recent passive transfer studies. We immunized rabbits and raised a high titer antiserum to the NC-1 domain of human type VII collagen. We injected this antibody into hairless immune competent mice, and the mice developed bullous skin disease with many of the features of EBA in humans.[17] The mice developed subepidermal blisters and lost nails on their feet. They also had circulating NC-1 antibodies in their blood and anti–NC-1 IgG antibody deposits at their DEJ. In addition, the mice had murine complement deposits at the DEJ induced by the autoantibody-antigen complex.[17] Another study by Sitaru and colleagues[18] showed that the injection of rabbit polyclonal antibodies to the NC-1 domain of mouse type VII collagen into mice also induced sub-epidermal skin blisters that were reminiscent of human EBA.[18] Further, we have also affinity purified human EBA autoantibodies against an NC-1 column and injected them into mice. The mice then developed clinical, histologic, immunologic and ultrastructural features akin to human EBA.[19] Taken together, these successful passive transfer experiments and the observations with bullous SLE strongly suggest that EBA autoantibodies are "pathogenic" and capable of causing epidermal-dermal separation in skin.

CLINICAL FINDINGS (Fig. 58-1)

If a patient presents with bullae on the skin with no reasonable explanation despite a thorough history and physical examination, three tests should be done: a skin biopsy for routine hematoxylin and eosin histology, a second biopsy juxtaposed to a lesion but on normal-appearing skin for DIF and a blood draw to test for antibodies against the BMZ and/or type VII col-

lagen by indirect immunofluorescence (IIF) or enzyme-linked immunosorbent assay (ELISA).

History

Cutaneous Lesions

The cutaneous lesions of EBA can be quite varied and can mimic other types of acquired autoimmune bullous diseases. The common denominator for patients with EBA is autoimmunity to type VII (anchoring fibril) collagen. Although the clinical spectrum of EBA is still being defined, there are at least five clinical presentations: (1) a classic presentation, (2) a bullous pemphioid (BP)-like presentation, (3) a cicatricial pemphigoid (CP)–like presentation, (4) a presentation reminiscent of Brunsting-Perry pemphigoid with scarring lesions and a predominant head and neck distribution, and (5) a presentation reminiscent of linear IgA bullous dermatosis or chronic bullous disease of childhood.

Classic Presentation

The classic presentation (Figs. 58-2 and 58-3A) is of a noninflammatory bullous disease with an acral distribution that heals with scarring and milia formation. This presentation is reminiscent of porphyria cutanea tarda (PCT; see Chap. 132) when it is mild and of the hereditary form of recessive dystrophic EB when it is severe (see Chap. 60). The classic form of EBA is thus a mechanobullous disease marked by skin fragility. These patients have erosions, tense blisters within noninflamed skin, and scars over trauma-prone surfaces such as the backs of the hands, knuckles, elbows, knees, sacral area, and toes (see Figs. 58-2, 58-3A, and 58-4). Some blisters may be hemorrhagic or develop scales, crusts, or erosions. The lesions heal with scarring and frequently with the formation of pearl-like milia cysts within the scarred areas (see Fig. 58-3A). Although this presentation may be reminiscent of PCT, these patients do not have other hallmarks of PCT, such as hirsutism, a photodistribution of the eruption, or scleroderma-like changes, and their urinary porphyrins are within normal limits. A scarring alopecia and some degree of nail dystrophy may be seen.

Although the disease is usually not as severe as that of patients with hereditary forms of recessive dystrophic EB, EBA patients with the classic form of the disease may have many of the same sequelae, such as scarring, loss of scalp hair, loss of nails, fibrosis of the hands and fingers, and esophageal stenosis.[23]

◀ **FIGURE 58-2** Patient with epidermolysis bullosa acquisita who has severe blistering, erosions, scarring, and milia formation on trauma-prone areas of her skin. This is the classic presentation.

Bullous Pemphigoid–Like Presentation (See Chap. 54)

A second clinical presentation of EBA is of a widespread, inflammatory vesiculobullous eruption involving the trunk, central body, and skin folds in addition to the extremities.[15] The bullous lesions are tense and surrounded by inflamed or even urticarial skin. Large areas of inflamed skin may be seen without any blisters and only erythema or urticarial plaques. These patients often complain of pruritus and do not demonstrate prominent skin fragility, scarring, or milia formation. This clinical constellation is more reminiscent of BP (see Figs. 58-3B and 58-4) than a mechanobullous disorder. Similar to BP, the distribution of the lesions may show an accentuation within flexural areas and skin folds.

Cicatricial Pemphigoid–Like Presentation (See Chap. 55)

Both the classic and BP-like forms of EBA may have involvement of mucosal surfaces. However, EBA also may present with such predominant mucosal involvement that the clinical appearance is reminiscent of CP (see Fig. 58-3C).[24] These patients usually have erosions and scars on the mucosal surfaces of the mouth, upper esophagus, conjunctiva, anus, or vagina with or without similar lesions on the glabrous skin.

Brunsting-Perry Pemphigoid–Like Presentation (See Chap. 55)

Brunsting-Perry cicatricial BP is a chronic, recurrent vesiculobullous eruption localized to the head and neck and characterized by residual scars, subepidermal bullae, IgG deposits at the DEJ, and minimal or no mucosal involvement. The antigenic target for the IgG autoantibodies, however, has not been defined. Nevertheless, a patient reported with this constellation of findings had IgG autoantibodies directed to anchoring fibrils below the lamina densa.[25] We have seen three additional patients with the features of Brunsting-Perry pemphigoid and autoantibodies directed to type VII collagen (unpublished observations). Therefore, it appears that EBA patients may present with a clinical phenotype of Brunsting-Perry pemphigoid (see Fig. 58-3D).

Immunoglobulin A Bullous Dermatosis–Like Presentation (See Chap. 56)

IgA bullous dermatosis–like presentation of EBA is manifested by a subepidermal bullous eruption, a neutrophilic infiltrate, and linear IgA deposits at the BMZ when viewed by DIF. It may resemble linear IgA bullous dermatosis (LABD), dermatitis herpetiformis, or chronic bullous disease of childhood and may feature tense vesicles arranged in an annular fashion and involvement of mucous membranes.[26] The autoantibodies are usually IgA, IgG, or both.

The diagnosis of these sub-epidermal blistering cases with IgA anti-type VII collagen antibodies showing linear IgA deposition at the BMZ is disputable. Some clinicians regard the patients as having purely LABD, whereas others regard them as having a subset of EBA. Further, the majority of EBA patients have low titer IgA antibodies in their blood directed against type VII collagen.

Childhood EBA is a rare disease. It has a variable presentation, including an LABD-like disease, a BP-like disease, and the classic mechanobullous EBA presentation. Although mucosal involvement is frequent and severe in

▲ **FIGURE 58-3** **A.** Classic presentation of epidermolysis bullosa acquisita with scarring and milia over trauma-prone areas of skin. **B.** Bullous pemphigoid–like presentation of epidermolysis bullosa acquisita with a widespread inflammatory vesiculobullous dermatosis. **C.** Cicatricial pemphigoid–like presentation of epidermolysis bullosa acquisita with a mucosal-centered bullous scarring eruption. **D.** Brunsting-Perry pemphigoid–like presentation of epidermolysis bullosa acquisita with bullous and scarring lesions predominantly on the head and neck.

childhood EBA, the overall prognosis is more favorable than in adult EBA.

Incidence of the Clinical Presentations of Epidermolysis Bullosa Acquisita

According to the authors' experience, approximately 25 percent of patients with EBA may present with a BP-like clinical appearance. The disease of some of these patients eventually smolders into a more noninflammatory mechanobullous form. However, both the classic and BP-like forms of the disease may co-exist in the same patient (Fig. 58-5). The clinical phenotype of EBA that is reminiscent of pure CP occurs in fewer than 10 percent of all EBA cases.

Related Physical Findings

EBA patients may have many physical findings similar to patients with hereditary dystrophic EB due to gene defects in the type VII collagen gene. These include oral erosions, esophageal strictures, hypo- and hyperpigmentation skin mottling, nail loss, milia formation, scarring, and a degree of fibrosis of the hands.

A number of published reports suggest that EBA may be associated with various systemic diseases[20] such as inflammatory bowel disease, SLE, amyloidosis, thyroiditis, multiple endocrinopathy syndrome, rheumatoid arthritis, pulmonary fibrosis, chronic lymphocytic leukemia, thymoma, diabetes, and other diseases in which an autoimmune pathogenesis has been implicated. At the University of North Carolina, Stanford, Northwestern, and University of Southern California, with a combined experience of following over 62 EBA pa-

▲ **FIGURE 58-4** An epidermolysis bullosa acquisita patient with involvement of the leg. Note bullae, erosions, and crusts.

▲ **FIGURE 58-5** An epidermolysis bullosa acquisita patient demonstrating two presentations of the disease: The classic mechanobullous presentation with erosions, scarring, and milia over the elbows and the more inflammatory bullous pemphigoid–like lesions on her trunk.

tients, it appears that inflammatory bowel disease is the systemic disease most frequently associated with EBA.

LABORATORY TESTS

Histopathology

Routine histologic examination of lesional skin obtained from EBA patients shows a sub-epidermal blister and a clean separation between the epidermis and dermis. The degree of inflammatory infiltrate within the dermis usually reflects the degree of inflammation of the lesion observed by the clinician. Lesions that are reminiscent of recessive dystrophic EB or PCT usually have a notable scarcity of inflammatory cells within the dermis. Lesions that are clinically reminiscent of BP usually have significantly more inflammatory cells within the dermis, and these cells may be a mixture of lymphocytes, monocytes, neutrophils, and eosinophils. The histology of EBA skin specimens obtained from BP-like lesions may be difficult to distinguish from BP itself.

Immunofluorescence

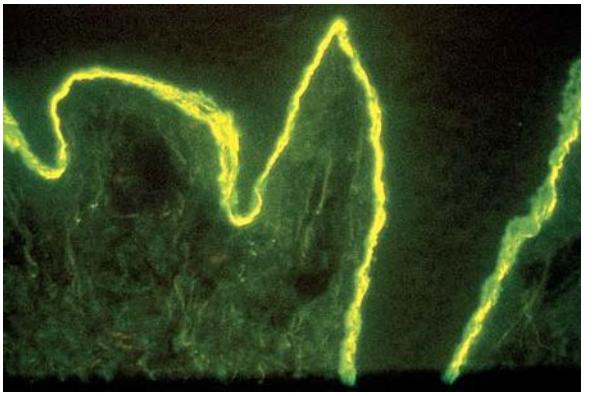
Patients with EBA have IgG deposits within the DEJ of their skin.[3,23] This is best detected by DIF of a biopsy specimen obtained from a perilesional site (Fig. 58-6). IgG is the predominant immunoglobulin class, but deposits of complement, IgA, IgM, factor B, and properdin also may be detected. The DIF staining demonstrates an intense linear fluorescent band at the DEJ. Yaoita et al.[2] have suggested that a positive DIF and IgG deposits within the sub-lamina densa zone are necessary criteria for the diagnosis of EBA.

Patients with PCT, which may mimic EBA clinically, frequently have IgG and complement deposits at the DEJ similar to those of EBA patients (see Chap. 132). However, the DIF feature that distinguishes PCT from EBA is that PCT skin also demonstrates immune deposits around the dermal blood vessels.

Patients with EBA may have autoantibodies in their blood directed against the DEJ.[3] These antibodies can be detected by IIF of the patient's serum on a substrate of monkey or rabbit esophagus or human skin and stain the DEJ in a linear fashion that may be indistinguishable from BP sera.[19]

Immunoelectron Microscopy

The localization of the immune deposits within the DEJ of the skin of EBA patients by immunoelectron microscopy is the "gold standard" for the diagnosis. As demonstrated by Nieboer et al.[22] and Yaoita et al.,[2] patients with EBA have immune deposits within the sub-lamina densa zone of the cutaneous BMZ. This localization is clearly distinct from the deposits in BP, which are higher up in the hemidesmosome area or lamina lucida area of the basement membrane. It is also distinct from CP, which has antigenic targets confined to the lamina lucida (see Chaps. 54 and 55).



◀ **FIGURE 58-6** Direct immunofluorescence staining for immunoglobulin G deposits in perilesional skin of an epidermolysis bullosa acquisita patient. Note the dense deposits within the dermal-epidermal junction (the epidermis is on top in this section).

Indirect Salt-Split Skin Immunofluorescence

When human skin is incubated in 1 *M* NaCl, the DEJ fractures cleanly through the lamina lucida zone. This fracture places the BP antigen on the epidermal side of the split and all other basement membrane structures on the dermal side of the separation. Salt-split skin substrate can be used to distinguish EBA and BP sera.[3]

If the serum antibody is IgG and labels the epidermal roof, the patient does not have EBA, and BP should be considered. If, on the other hand, the antibody labels the dermal side of the separation, the patient usually has either EBA or bullous SLE. The latter can be ruled out by other serology and by clinical criteria.

Direct Salt-Split Skin Immunofluorescence

Perilesional skin incubated in cold 1 *M* NaCl is fractured through the DEJ, which effectively places the BP antigen (and any associated immune deposits) on the epidermal roof and the EBA antigen (and any associated immune deposits) on the dermal floor of the separation.[23] If the patient has EBA, immune deposits are detected on the dermal side of the separation by a routine DIF method using fluorescein-conjugated anti-human IgG.

Western Immunoblotting

Antibodies in EBA sera bind to a 290-kd band in Western blots of human skin basement membrane proteins containing type VII collagen, whereas sera from all other primary blistering diseases do not.[3] This band is the α chain of type VII collagen. Often, a second band of 145 kd is labeled with EBA antibodies. This band is the amino-terminal globular NC-1 domain of the type VII collagen α chain, which is rich in carbohydrate and contains the antigenic epitopes of EBA autoantibodies, bullous SLE autoantibodies, and monoclonal antibodies against type VII collagen.[10]

Enzyme-Linked Immunosorbent Assay

Chen et al.[32] have produced milligram quantities of recombinant, purified, post-translationally modified NC-1 in stably transfected human cells and have used this NC-1 to develop an ELISA for autoantibody detection in EBA patients and in patients with bullous SLE. This new ELISA is more sensitive than immunofluorescence and Western blotting, and yet it is very specific for antibodies to type VII collagen.

DIFFERENTIAL DIAGNOSIS (Box 58-1)

Because EBA has been described in infants and children, it is worth considering that a patient thought to have genetic dystrophic EB just might be a rare childhood patient with EBA. This can be ruled out by the antibody tests out-

Box 58-1

Differential Diagnosis of Epidermolysis Bullosa Acquisita

Most Likely

- Porphyria cutanea tarda
- Pseudo-porphyria cutanea tarda
- Bullous pemphigoid
- Cicatricial pemphigoid

Consider

- Linear immunoglobulin A bullous disease
- Brunsting-Perry pemphigoid
- Bullous systemic lupus erythematosus

lined in the section Laboratory Tests. PCT can look clinically very much like classic EBA and can be ruled out by a urine or plasma test for uroporphyrins. Pseudo-PCT, usually caused by drugs such as nonsteroidal anti-inflammatory agents, can look similar to EBA with skin fragility, erosions, and blisters over trauma-prone areas, scarring, and milia formation. Nevertheless, the DIF appears different in that pseudo-PCT, like PCT, shows IgG deposits at both the BMZ at the DEJ and around dermal blood vessels (which are not stained in EBA).

The BP-like EBA can be eliminated by several methods listed above, but the first-line test would be indirect and direct salt-split immunofluorescence.

DIAGNOSIS

The diagnostic criteria developed by Yaoita et al.[2] for the diagnosis of EBA still stand. These criteria, with slightly updated modifications, are shown in Table 58-1.

Alternatives for the last item are indirect or direct salt-split skin immunofluorescence, Western blotting, and ELISA.

COMPLICATIONS

The complications caused by EBA include secondary skin infections, usually due to *Staphylococcus* or *Streptococcus*, because the blisters and erosions compromise the skin's barrier. Scarring and milia formation are naturally occurring complications or sequelae of the deep blistering process. Severe EBA patients may develop significant fibrosis of the hands with decreased range of motion of the palm and digits. Because of wounds and fibrosis of the soles of the feet and toes, some EBA patients have difficulty walking. Many patients with EBA lose their fingernails. EBA patients with significant mucosal involvement may develop esophageal strictures.

TABLE 58-1

Diagnostic Criteria for Epidermolysis Bullosa Acquisita

- A bullous disorder within the clinical spectrum outlined earlier (see Clinical Findings).
- No family history of a bullous disorder.
- Histology showing a sub-epidermal blister.
- Deposition of immunoglobulin G deposits within the dermal-epidermal junction (i.e., a positive direct immunofluorescence of perilesional skin).
- Immunoglobulin G deposits localized to the lower lamina densa and/or sub-lamina densa zone of the dermal-epidermal junction when perilesional skin is examined by direct immunoelectron microscopy.

TREATMENT

EBA usually responds poorly to treatment. Supportive therapy is warranted in all patients with EBA. This includes instruction in open wound care and strategies for avoiding trauma. Patients should be warned not to overwash or overuse hot water or harsh soaps and to avoid prolonged or vigorous rubbing of their skin with a washcloth or towel. In some patients, it appears that prolonged sun exposure may aggravate or promote new lesions on the dorsal hands and knuckles. Thus, avoidance of prolonged sun exposure and the use of sunscreens are helpful. The patient should be educated to recognize localized skin infections and to seek medical care and antibiotic therapy promptly when they occur.

EBA patients are often refractory to high doses of systemic glucocorticoids, azathioprine, methotrexate, and cyclophosphamide, especially when they have the classic mechanobullous form of the disease. These agents may be somewhat helpful in controlling EBA when it appears as an inflammatory BP-like disease. Some EBA patients improve on dapsone, especially when neutrophils are present in their dermal infiltrate.

Cyclosporine has been shown to be beneficial in EBA.[33] However, the long-term toxicity of this drug limits its use.

There are also independent reports of EBA patients responding to high doses of colchicine.[34] This is often used as a first-line drug because its side effects are relatively benign compared with other therapeutic choices. Diarrhea is a common side effect of colchicine, however, which makes it difficult for many patients to achieve a high enough dose to control the disease. Moreover, because of this side effect, we are hesitant to use colchicine in EBA patients who also have inflammatory bowel disease. In addition, there are patients who do not respond to colchicine. Colchicine is a well-known microtubule inhibitor, but it also appears to have properties that have the potential to inhibit antigen presentation to T cells, which could downregulate autoimmunity.

Photopheresis has been used in Sézary syndrome, mycosis fungoides, and a variety of autoimmune bullous diseases (see Chap. 239). Photopheresis improves the clinical features of EBA and remarkably lengthens the suction blistering times of the patients, suggesting an improvement in their dermal-epidermal adherence.[35]

Intravenous Ig has been used in dermatomyositis, an entity in which autoimmunity may play a role. Intravenous Ig has been reported to be effective in some patients with EBA.[36] The mechanism by which γ globulin may invoke a positive response in EBA is unknown.

The anti–TNF-α biologics (such as infliximab; see Chap. 235) and anti CD antibodies against B cells have been tried in EBA with some success in limited open trials. Box 58-2 outlines treatment options in EBA that have some support in the medical literature.

Box 58-2

Treatments for Epidermolysis Bullosa Acquisita (EBA)

MEDICATION	DOSE RANGE
Colchicine[a]	0.6–3.0 mg/day
Cyclosporine A	6 mg/kg/day
Dapsone[b]	100–300 mg/day
Cytoxan	50–200 mg/day
Prednisone[c]	1.0–1.5 mg/kg
Intravenous immunoglobulin[d]	3 g/kg divided over 5 days
Infliximab	5 mg/kg at 0, 2, 4, and 6 wk

[a]Must start with 0.4–0.6 mg/day and each 1–2 wk double this dose as tolerated. When patient develops diarrhea, back off 1 tablet (0.4–0.6 mg).
[b]Begin at 25 mg/day and double each week after the complete blood count and liver function tests. Most patients need between 100–250 mg/day. Increasing the dose slowly helps the patient tolerate the anemia that develops (i.e., less orthostatic lightheadedness, etc.). Expect a 1- to 2-g drop in the patient's hemoglobin on therapeutic doses.
[c]Usually does not help the classic, mechanobullous type of EBA with minimal inflammation. However, it may be somewhat helpful in the bullous pemphigoid–like type of EBA.
[d]Intravenous immunoglobulin is given over 4–5 days every month for 5 or 6 mo to give it an adequate trial.

CHAPTER 59

Dermatitis Herpetiformis

Russell P. Hall III
Stephen I. Katz

EPIDEMIOLOGY

Dermatitis herpetiformis (DH) is characterized by an intensely itchy, chronic papulovesicular eruption that usually is distributed symmetrically on extensor surfaces. The disease can be clearly distinguished from the other sub-epidermal blistering eruptions by histologic, immunologic, and gastrointestinal criteria. The prevalence of DH in various Caucasian populations varies between 10 and 39/100,000 persons.[1–3] It may start at any age, including childhood; however, the second, third, and fourth decades are the most common. After presentation, DH persists indefinitely, although with varying severity. Patients with DH have an associated gluten-sensitive enteropathy (GSE) that is usually asymptomatic.

HISTORY

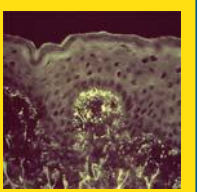
ETIOLOGY AND PATHOGENESIS

In 1999, Dieterich et al. identified antibodies to tissue transglutaminases (Tgases) in the sera from DH patients.[18] Distinguishing between various types of Tgases enabled Sardy et al. in 2002 to demonstrate that epidermal Tgase is the dominant autoantigen in DH.[19]

Gluten, a protein found in wheat, barley, and rye, plays a critical role in the pathogenesis of DH. Oats, long thought to contain gluten and play a role in inducing DH lesions, have been shown to be devoid of toxicity in patients with DH.[20,21] In 1966, Marks et al. first noted a gastrointestinal abnormality in patients with DH.[11] Shortly thereafter, it was shown that the lesion was reversible by avoidance of the dietary protein gluten.[13,22] Initially, the intestinal abnormality was thought to be present in 60 percent to 75 percent of DH patients. However, this view has been modified in two ways. First, the diagnostic criteria for DH have been delineated more precisely, and second, it can be shown that certain patients without apparent gastrointestinal pathology can be "induced" to develop gastrointestinal lesions by subjecting them to a large gluten intake; such patients have been said to have latent celiac sprue.[23] Thus, most patients with DH have a gastrointestinal abnormality similar (if not identical) to celiac disease, however minimal that may be when the patient is ingesting a normal gluten load. As in celiac disease, there is an increased density of small bowel intraepithelial T cells with a γ/δ T-cell receptor in the jejunum of patients with DH.[24] The finding that T-cell lines from patients with DH produce significantly more interleukin 4 (IL-4) than those from patients with GSE and that gut biopsies from symptomatic patients with isolated GSE showed increased expression of interferon-γ suggests that different cytokine patterns may play a role in the varied clinical manifestations of these two diseases.[25,26] Systemic evidence of the gut mucosal immune response has also been found in the serum and the skin of patients with DH. Patients with DH on regular gluten-containing diets have been found to have increased serum IL-2 receptor levels and serum IL-8 levels,[27,28] increased endothelial cell E-selectin expression in skin and an increased expression of CD11b on circulating neutrophils.[25,27,29] These systemic manifestations of the gut mucosal immune response may play a role in creating the pro-inflammatory environment in the skin necessary for the development of skin lesions.

The GSE seen in DH patients probably relates to the immunoglobulin A (IgA) deposits that are found in the skin of these patients, although a direct relationship has not been demonstrated. It is known that patients with both GSE and DH have antibodies to Tgases that are thought to be the major autoantigens in these diseases.[18,30] There appears to be a predilection for the autoantibodies to bind to epidermal Tgase in DH, whereas the predilection is for autoantibodies to bind tissue Tgase in patients with isolated GSE.[19] The mechanism whereby IgA anti-epidermal Tgase deposits in DH skin is not known. One

DERMATITIS HERPETIFORMIS AT A GLANCE



- Intensely itchy, chronic papulovesicular eruption distributed symmetrically on extensor surfaces.
- Characterized histologically by dermal papillary collections of neutrophils (microabscesses).
- Granular immunoglobulin A deposits in normal-appearing skin are diagnostic for dermatitis herpetiformis.
- Most, if not all, dermatitis herpetiformis patients have an associated gluten-sensitive enteropathy.
- The rash responds rapidly to dapsone therapy and, in many patients, to strict adherence to a gluten-free diet.

long-standing hypothesis has been that IgA containing circulating immune complexes are responsible for the IgA deposits in DH skin. The recent discovery of IgA anti-epidermal Tgase antibodies has suggested that IgA-epidermal Tgase immune complexes may be depositing in the skin of DH patients. Only a minority of DH patients, however, have been found to have IgA and epidermal tissue Tgase deposits co-localized in a perivascular pattern.[31,32] In addition, perivascular neutrophil deposits that are typically found with the perivascular deposition of immune complexes rarely occur in patients with DH.[33] These findings suggest an alternative hypothesis that IgA anti-epidermal Tgase may directly bind in the skin to epidermal tissue Tgase. The exact mechanism of IgA binding in the skin of patients with DH, however, remains unknown.

Whether the IgA skin deposits play a role in the pathophysiology of blister formation is not known. The finding of IgA and complement in almost all skin sites, not only in lesional skin, makes one postulate that if IgA (either alone or as a part of an immune complex) does play a role, additional factors are still needed to explain the initiation of lesions. Takeuchi et al. have demonstrated that minor trauma to skin results in increased expression of IL-8 and E-selectin, both of which may predispose to a neutrophilic inflammatory infiltrate.[34] These findings, coupled with the typical appearance of DH lesions on extensor surfaces at sites of trauma, suggest local cytokine/chemokine production after trauma may be one of the inciting factors of DH skin lesions. It may be that after the initial neutrophilic infiltrate binds to the cutaneous IgA, factors such as cytokines, chemokines, and proteases are released that both directly result in blister formation and induce basal keratinocytes to produce collagenases or stromelysin-1 that further contributes to the formation of blisters.[35,36] Other studies have suggested that T cells may play a role in the pathogenesis of the skin lesions; however, no specific T-cell responses to gluten have been detected.[37,38]

It has been known for some time that iodides, administered orally, can exacerbate or elicit eruptions of DH, and this has, in former times, been used for diagnostic purposes. The availability of immunopathologic techniques for the detection of IgA deposits in skin has made such provocation tests obsolete.

The absence of animal models of DH, either naturally occurring or developed in the laboratory, has limited advances in our understanding of the pathogenesis of DH. Recently, Marietta and coworkers reported a new mouse model for DH. They reported an HLA-DQ8 transgenic non-obese diabetic mouse that when immunized with gluten developed neutrophilic skin lesions along with cutaneous deposits of IgA. In addition, withdrawal of dietary gluten resulted in resolution of the skin lesions.[39] Further investigation of this mouse model may provide important information regarding the pathogenesis of DH.

▲ **FIGURE 59-1** Dermatitis herpetiformis. Extensive eruption with grouped papules, vesicles, and crusts on the back.

CLINICAL MANIFESTATIONS

The primary lesion of DH is an erythematous papule, an urticaria-like plaque, or, most commonly, a vesicle (Figs. 59-1, 59-2, and 59-3). Large bullae occur infrequently. Vesicles, especially if they occur on the palms, may be hemorrhagic. The continual appearance and disappearance of lesions may result in hyperpigmentation and hypopigmentation. Patients may present with only crusted lesions, and a thorough search may not reveal a primary lesion. The herpetiform (herpes-like) grouping of lesions is often present in some areas (see Figs. 59-1 and 59-3), but patients also may have many individual nongrouped lesions.

Symptoms vary considerably from the usually severe burning and itching in most patients to the almost complete lack of symptoms in a rare patient. Most patients usually can predict the eruption of a lesion as much as 8 to 12 hours before its appearance because of localized stinging, burning, or itching.

▲ **FIGURE 59-2** Dermatitis herpetiformis. Papules, vesicles, and crusts on knees.

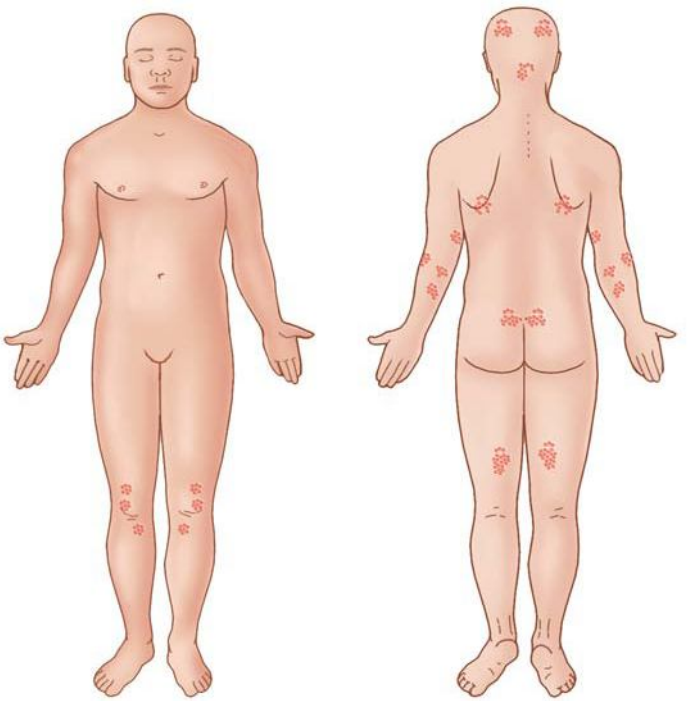
The usual symmetric distribution of lesions on elbows, knees, buttocks, shoulders, and sacral areas is seen in most patients at one time or another (see Figs. 59-1 to 59-4). Although these regions are affected most commonly, most patients have scalp lesions and/or lesions in the posterior nuchal area. Another commonly affected area is the face and facial hairline. Mucous membrane lesions are uncommon, as are lesions on the palms and soles.

LABORATORY TESTS

In Vivo–Bound Immunoglobulin A and Complement

After Cormane demonstrated that both perilesional and uninvolved skin of patients with DH contained granular (or fibrillar) Ig deposits located in dermal papillary tips, van der Meer found that the most regularly detected Ig class in DH skin

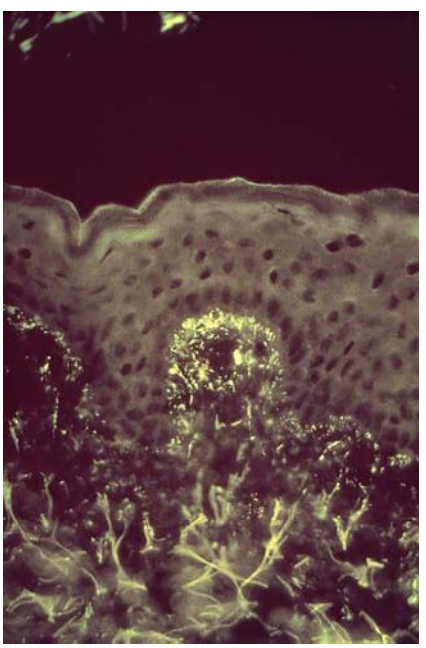
▲ **FIGURE 59-3** Dermatitis herpetiformis. This patient has many firm-topped vesicles and bullae, some erosions, and residual hyperpigmentation. Some of the vesicles are arranged in an annular pattern.



▲ **FIGURE 59-4** Dermatitis herpetiformis. Pattern of distribution.

was IgA (Fig. 59-5).[9,10] IgA deposits have, however, not been seen in the skin of patients with isolated GSE (celiac disease).[40]

Finding granular IgA deposits in normal-appearing skin is the most reliable criterion for the diagnosis of DH.[33,41] These IgA deposits are unaffected by treatment with drugs but may decrease in intensity or disappear after long-term adherence to a gluten-free diet.[42,43] The IgA deposits are not uniformly intense throughout the skin and may be detected more easily in normal-appearing skin near active lesions.[44] In DH, other immunoglobulins sometimes are bound to the skin in the same areas as the IgA.[41] IgA deposits also may be seen in the skin of patients with bullous pemphigoid, scarring pemphigoid, Henoch-Schönlein purpura, and alcoholic liver disease, although in different patterns of distribution than those seen in DH.



▲ **FIGURE 59-5** Dermatitis herpetiformis. Direct immunofluorescence showing granular dermal papillary deposits of immunoglobulin A.

Because of the IgA skin deposits and the association between DH and GSE (celiac disease), several groups have studied the IgA subclasses in DH. IgA1 is the predominant (or exclusive) subclass that has been identified in the skin of DH patients.[45,46] Most IgA1 is produced in the bone marrow, whereas most IgA2 is produced at mucosal sites. This does not negate the possibility that the IgA1 in skin may still be of mucosal origin because IgA1 is the predominant IgA subclass of IgA antibodies directed against dietary proteins produced in gut secretions in patients with DH.[47,48]

The third component of complement (C3) is frequently found in the same location as IgA. The presence of C3 in both perilesional and normal-appearing skin is not affected by treatment with dapsone (diaminodiphenyl sulfone), but C3 may not be detectable after treatment with a gluten-free diet.[43,49,50] C5 and components of the alternative complement pathway also may be seen in areas corresponding to the IgA deposits. The C5-C9 membrane attack complex, which is formed as the terminal event in complement activation, is also seen in normal-appearing and perilesional skin of patients.[51]

The exact site of the IgA deposits in DH skin has been studied by immunoelectron microscopy. Early studies indicated that IgA is preferentially associated with bundles of microfibrils and with anchoring fibrils of the papillary dermis immediately below the basal lamina.[52,53] More recent studies, however, have indicated that some or almost all of the IgA deposits are related to nonfibrillar components of skin and other connective tissues.[52–56] There is also no agreement as to whether the IgA deposits in DH co-localize to fibrillin, a major component of the elastic microfibrillar bundles.[56,57]

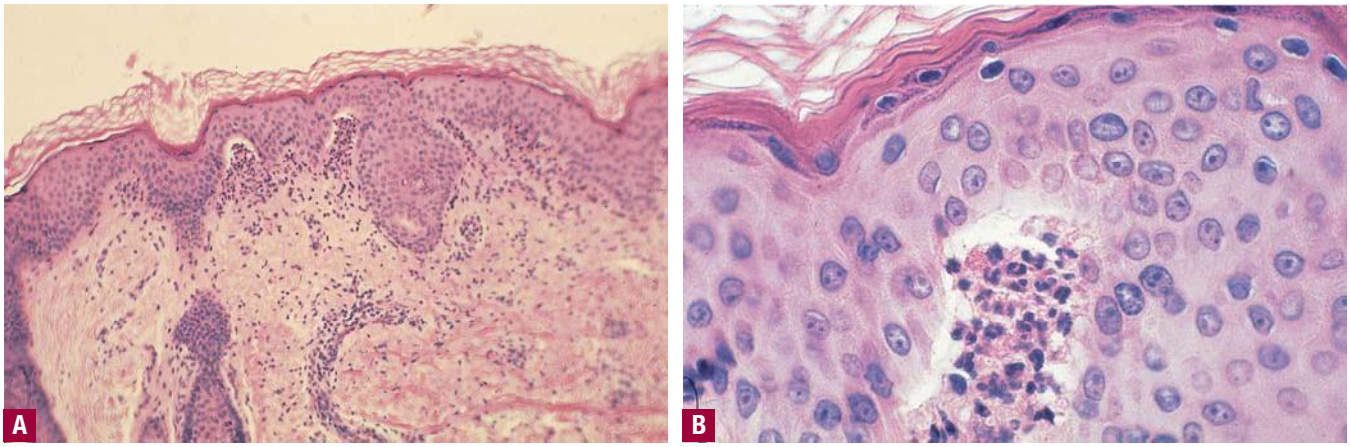
Serum Studies

Antireticulin antibodies of the IgA and IgG classes have been detected in the sera of 17 percent to 93 percent of patients with DH and in higher percentages of patients with other diseases, especially celiac disease.[58] Thyroid microsomal antibodies and anti-nuclear antibodies also have been detected in increased incidence in the sera of patients with DH.[59,60] Putative immune complexes have been detected in the sera of 25 percent to 40 percent of patients.[61,62]

Chorzelski et al. have described an IgA antibody that binds to an intermyofibril substance (endomysium) of smooth muscle.[63] The nature of this antigen has been identified recently by the studies of Sardy et al., who showed that these IgA autoantibodies have specificity for Tgases, particularly epidermal-specific Tgases.[19]

Immunogenetic Findings

There is a marked increase in the incidence of certain major histocompatibility complex antigens in patients with DH. Worldwide studies have found that 77 percent to 87 percent of DH patients have HLA-B8 (compared with 20 percent to 30 percent of unaffected individuals).[15,64–66] In addition, the class II major histocompatibility complex antigens HLA-DR and -DQ are associated with DH even more frequently than is HLA-B8.[67,68] Park et al. reported that more than 90 percent of patients expressed Te24, which was later shown to be similar to HLA-DQw2, and this finding has been confirmed by others.[69] Molecular studies indicate that susceptibility to DH is not associated with a



▲ **FIGURE 59-6** Dermatitis herpetiformis. Biopsy of an early lesion showing dermal papillary collections of neutrophils and eosinophils and sub-epidermal vesiculation at low (**A**) and high (**B**) magnification.

unique HLA-DQw2 molecule.[70] Virtually all patients with DH have genes that encode the HLA-DQ (α1*0501, β1*02) or the HLA-DQ (α1*03, β1*0302) heterodimers, a pattern identical to that seen in celiac disease.[70,71] This strong association between susceptibility genes and DH and GSE is important clinically and pathophysiologically in that there is a strong concordance of these two diseases in monozygotic twins.[72] Furthermore, first-degree relatives of both DH and GSE patients are often (4 percent to 5 percent) affected with one or the other of these diseases.[73]

Histopathology

The histology of an early skin lesion (clinically nonvesicular) is characterized by dermal papillary collections of neutrophils (microabscesses), neutrophilic fragments, varying numbers of eosinophils, fibrin, and, at times, separation of the papillary tips from the overlying epidermis (Fig. 59-6). In addition, in such early lesions, the upper and middle dermal blood vessels are surrounded by a lymphohistiocytic infiltrate as well as some neutrophils and an occasional eosinophil.[7,8] At times, early lesions may be difficult or impossible to differentiate from those of linear IgA disease (see Chap. 56), the bullous eruption of lupus erythematosus (see Chap. 156), bullous pemphigoid (see Chap. 54), or the neutrophil-rich form of epidermolysis bullosa acquisita (see Chap. 58). The histology of older lesions shows subepidermal vesicles that may be impossible to differentiate from other subepidermal bullous eruptions, such as bullous pemphigoid, erythema multiforme, bullous drug eruption, and pemphigoid gestationis. Immunofluorescent localization and ultrastructural studies of the site of blister formation in DH have demonstrated that the blister forms above the lamina densa—within the lamina lucida. This is thought to occur because the lamina lucida is the most vulnerable component of the dermal-epidermal junction.[74,75]

ASSOCIATED PROBLEMS

Gastrointestinal Manifestations

It is now well accepted that most, if not all, DH patients have an associated gastrointestinal abnormality that is caused by gluten sensitivity.[12,13,65] The pathology of the GSE associated with DH and that in isolated GSE (GSE unassociated with DH) is essentially the same, although the lesion in the latter is usually much more severe; this applies to the epithelial cell derangement as well as to the character of the lymphoplasmacytic infiltrate. In addition, the distribution of the gastrointestinal lesion in the small intestine is, as a general rule, more widespread in celiac disease. The functional changes in the bowel and clinical sequelae encountered in the GSE associated with DH and those encountered in celiac disease are similar but again differ in degree, those in the latter being more severe. Thus, in DH one observes steatorrhea (20 percent to 30 percent of patients), abnormal D-xylose absorption (10 percent to 33 percent of patients), and occasional anemia secondary to iron or folate deficiency. In patients not taking dapsone or related drugs, the latter is usually due to malabsorption. Studies using elemental diets (see Elemental and Other Diet Therapy) in the treatment of DH have questioned the critical role attributed to gluten in the pathogenesis of this disease. In addition to the small intestinal lesion, patients with DH have an increased incidence of achlorhydria and atrophic gastritis.[76,77] Reports of pernicious anemia and antibodies to gastric parietal cells are thus likely to be due to more than chance.

Malignancy

Leonard et al. have reported an increased frequency of malignancies, especially gastrointestinal lymphomas, and Collin et al. have reported a significant increase in non-Hodgkin lymphomas in patients with DH.[78,79] A combined retrospective study from both these groups suggests a protective role for a gluten-free diet against gastrointestinal lymphomas.[80] Hervonen and co-workers reported that 1 percent of 1104 patients with DH developed a lymphoma from 2 to 31 years after the diagnosis of DH. Of interest, only two lymphomas were of the enteropathy-associated type, whereas eight were B-cell type lymphomas and one was unclassified. The patients with DH that developed lymphoma had adhered to a gluten-free diet less strictly than patients without lymphoma.[81] Recently, Viljamaa and coworkers reported on the rate of malignancies and mortality in patients with DH with a 30-year population-based study.[82] They reported no difference in overall malignancy rate in patients with DH from the general population; however, there was an increase in non-Hodgkin lymphomas. Of interest, the mortality rate for patients with DH was lower than in the general population. In total, these studies suggest that patients with DH are at increased, albeit low, risk for lymphoma and that this risk is not restricted to enteropathy-associated lymphomas.

Other Diseases

In addition to celiac disease, atrophic gastritis, and pernicious anemia (see Gas-

trointestinal Manifestations), DH patients have a higher incidence of other autoimmune diseases such as thyroid disease, insulin-dependent diabetes, lupus erythematosus, Sjögren syndrome, and vitiligo.[60,83,84] This predilection for associated autoimmune diseases may be due to the high frequency of the 8.1 ancestral haplotype in these DH patients.[85]

Neurologic disease has been reported in patients with isolated celiac disease, including epilepsy, ataxia, and dementia; however, confirmation of these findings awaits confirmation with large epidemiologic studies.[86] Some authors have proposed that patients with DH may be at higher risk for these neurologic complications due to long-standing ingestion of gluten; however, Wills and co-workers found no evidence of immune-mediated neurologic disease in their evaluation of patients with DH.[87]

Patients with untreated celiac disease have also been found to have an increased frequency of bone loss.[88] Patients with DH frequently continue on gluten-containing diets with a long-standing, albeit low grade, malabsorption. Di Stefano demonstrated a significantly reduced bone mineral density in patients with DH on gluten-containing diets.[89] These findings suggest that patients with DH be followed closely and those on gluten-containing diets be screened for potential decrease in bone density. If decreased bone mineral density is found, patients should be encouraged to begin a gluten-free diet.

DIFFERENTIAL DIAGNOSIS

DH may be confused with numerous other conditions because of its pleomorphic manifestations and the occasional lack of diagnostic lesions (Box 59-1). Neurotic excoriations, eczema, papular urticaria, transient acantholytic dermatosis, pemphigoid, pemphigoid gestationis, erythema multiforme, and various other dermatoses can be differentiated easily on the basis of histologic and immunologic criteria. Linear IgA disease may be more difficult to differentiate clinically and histologically, but it is distinctive immunologically. A high index of suspicion is very helpful in that even in the absence of primary lesions, DH can be diagnosed based on the typical in vivo–bound granular IgA deposits in normal-appearing skin.

TREATMENT

Sulfones

Diaminodiphenyl sulfone (dapsone), sulfoxone (diasone—not available in the United States), and sulfapyridine provide prompt improvement in symptoms and signs of the disease. Symptoms may abate in as few as 3 hours or as long as a few days after the first pill is taken, and new lesions no longer erupt after 1 to 2 days of treatment. Exacerbations occur from hours to days after cessation of treatment. This response to therapy was, for a long time, the most important element in making a diagnosis. The preferred treatment for an adult is dapsone at an initial dosage of 100 to 150 mg/day (this usually can be taken once a day). An occasional patient may require 300 to 400 mg of dapsone for initial improvement. Patients should be instructed to take the minimal dose required to suppress signs and symptoms. Not all patients require daily treatment; in rare cases, 25 mg weekly is sufficient. Sulfapyridine, in a dosage of 1.0 to 1.5 g daily, is particularly useful in patients intolerant of dapsone, in elderly patients, and in those with cardiopulmonary problems. The pharmacology, mechanism(s) of action, adverse effects, and monitoring of dapsone are discussed in Chap. 226. It is important to know that nonsteroidal anti-inflammatory drugs often exacerbate DH, even in patients taking dapsone.[90]

Gluten-Free Diet

EFFECT ON THE SMALL INTESTINE There is no doubt that the intestinal lesion in DH responds to dietary gluten withdrawal. The time course of the response in adults with DH is the same as that in adults with celiac disease.

EFFECT ON THE SKIN DISEASE Strict adherence to a gluten-free diet will, after variable periods of time (from 5 months to 1 year), reduce or completely eliminate the requirement for medication in most, but not all, patients. The most extensive early study by Fry et al. has been confirmed by several groups.[14] However, it is only the very highly motivated patient who can adhere to the diet, which requires counseling by an individual who is very familiar with its use.

Elemental and Other Diet Therapy

Studies in small numbers of DH patients have indicated that elemental diets (composed of free amino acids, short-chain polysaccharides, and small amounts of triglycerides) can be very beneficial in alleviating the skin disease within a few weeks.[91,92] The beneficial effect on the skin disease may be achieved even if the patient ingests large amounts of gluten.[91] Unfortunately, elemental diets are difficult to tolerate for long periods. Interestingly, complete resolution of the skin lesions of DH has also been reported by adherence to the high-protein, unlimited fat, low-carbohydrate diet popularized as the "Atkins Diet."[93] Further studies are needed to confirm this report.

CHAPTER 60

Inherited Epidermolysis Bullosa

M. Peter Marinkovich
Eugene A. Bauer

Inherited epidermolysis bullosa (EB) is a family of diseases that have the common feature of blistering in response to mild trauma.[1] Patients with EB can show blistering in the form of small vesicles or larger bullae, which can occur on both the cutaneous surfaces as well as on the mucosal tissues. The fragility of the skin and mucosa and the traumatic production of painful blisters are shared by all EB cases. However, the distribution of the involvement, the depth of blister formation, and the severity of the blistering process varies with the different EB subtypes and depends on the underlying heritable molecular defect. EB diseases also vary in the way in which blistered areas heal. The wound repair responses are often abnormal and can eventuate into chronic erosions, hypertrophic granulation tissue, scarring, or even invasive carcinoma. Although the milder EB subtypes are associated with a normal lifespan and little or no internal involvement, the most severe, recessively inherited forms are mutilating, multiorgan disorders that threaten both the quality and length of life.[2,3]

ETIOLOGY AND PATHOGENESIS

Overview

EB arises from defects of attachment of basal keratinocytes to the underlying dermis (see Chap. 51). These defects can arise from inside the keratinocyte plasma membrane or extracellularly in the dermal-epidermal basement membrane zone (BMZ). The etiology and pathogenesis of EB cannot be understood without an appreciation of the organization of the dermal-epidermal BMZ. Many tissues, such as the skin and cornea, which are subjected to external disruptive forces, contain a complex BMZ composed of a group of specialized components that combine together to form anchoring complexes (Fig. 60-1). At the most superior aspect of the BMZ, keratin-containing intermediate filaments of the basal cell cytoskeleton insert upon electron dense condensations of the basal cell plasma membrane, termed *hemidesmosomes*. Anchoring filaments span the lamina lucida connecting hemidesmosomes with the lamina densa and anchoring filaments. At the most inferior aspect of the BMZ, type VII collagen-containing, anchoring fibrils extend from the lamina densa into the papillary dermis and combine with the lamina densa and anchoring plaques, trapping interstitial collagen fibrils. Thus, the cutaneous BMZ connects the extensive basal cell cytoskeletal network with the abundant network of interstitial collagen fibrils in the dermis.[19,20]

CLINICAL FINDINGS

A classification of EB is made based on the ultrastructural level within which the cleavage plane of the blister occurs. EB has been traditionally classified according to the level of BMZ separation on transmission electron microscopy (TEM) into simplex, junctional, and dystrophic sub-types (Fig. 60-2). However, a fourth category has been proposed, hemidesmosomal EB, which takes into account patients who show intraepidermal blistering just above the basal plasma membrane (see Fig. 60-2E).[67] Although traditionally the diagnostic "gold standard" for grouping EB has been electron microscopy, immunomapping of basement membrane antigens as viewed by indirect immunofluorescence (IDIF) can also be quite useful in distinguishing sub-types of EB. Within each of these groups, there are several distinct types of EB based on clinical, genetic, histologic, and biochemical evaluation.[68] These findings are summarized in the following sections (Table 60-1).

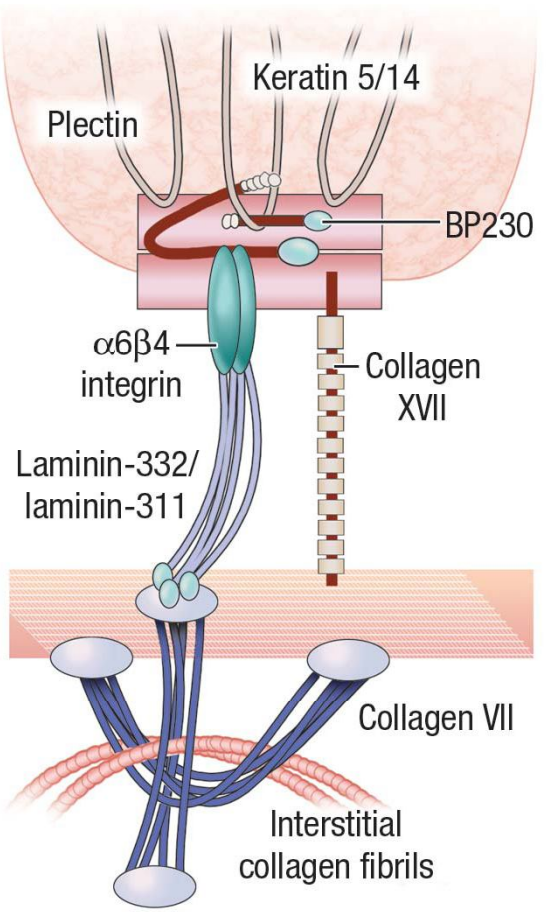
EPIDERMOLYSIS BULLOSA AT A GLANCE

- Family of inherited genodermatoses characterized by blistering in response to minor trauma.
- Blistering level categorizes as simplex, hemidesmosomal, junctional, and dystrophic sub-types.
- Cutaneous involvement varies from localized to widespread blistering, depending on sub-type.
- Extra-cutaneous involvement varies from none to severely debilitating or lethal.
- Oropharynx, trachea, esophagus, eyes, teeth, nails, and hair can be involved, depending on sub-type.
- Diagnosis is made by immunofluorescence and/or electron microscopy followed by DNA analysis.

Epidermolysis Bullosa Simplex

EBS is a group characterized by intraepidermal blistering and is associated with keratin gene mutations. The disease phenotypes range from mild to severe among different subgroups.[69] The three most common EBS types are dominantly inherited and include generalized (Koebner), localized (Weber-Cockayne), and herpetiform (Dowling-Meara). There are several uncommon varieties, which include the EBS Ogna variant, EBS superficialis, and EBS with mottled pigmentation (see Table 60-1).

GENERALIZED EPIDERMOLYSIS BULLOSA SIMPLEX Also known as the *Koebner variant*, generalized EBS shows an onset of blistering at birth or at latest during early infancy. The hands, feet, and extremities usually show the most involvement. Lesions often heal with post-inflammatory



◀ **FIGURE 60-1** Schematic of the components of the dermal-epidermal basement membrane on the left compared with ultrastructural appearance of basement membrane morphologic entities on the right. BP230 = bullous pemphigoid antigen 230 KD.

hyper- or hypopigmentation and, although occasional atrophy and milia can occur, they are rare and much less frequent than in EB herpetiformis. Palmar-plantar hyperkeratosis and erosions may be present (Fig. 60-3). Thickening of the soles is common but often does not present until later childhood. The oral mucosa sometimes shows mild erosive activity, but this usually improves with increasing age. There is not severe growth retardation in this EB sub-type.

EPIDERMOLYSIS BULLOSA HERPETIFORMIS EB herpetiformis is also known as the *Dowling-Meara form of EBS*. It presents at birth and, like the Koebner variant, it has a generalized distribution. The Dowling-Meara form is regarded as the most severe of the EBS sub-types (Fig. 60-4). It differs from the Koebner variant, however, in that the oral mucosa is more often involved, occasionally showing extensive erosions. Milium formation may sometimes occur in infancy in patients with this sub-type. However, this post-wound phenomenon usually resolves later in childhood. The disease received its name due to the spontaneous appearance of grouped or "herpetiform" blisters. These occur on the trunk and proximal extremities and heal without scarring. It should be noted that when patients are young and show a generalized blistering, this herpetiform pattern may not be seen. Therefore, its absence should not be used as a basis to exclude this EB sub-type. EB herpetiformis often shows nail involvement, and blistering is not uncommonly hemorrhagic. In this disease, nails may become shed and may re-grow with dystrophy. Interestingly, although heat exacerbates the blistering in other EBS subtypes, it does not appear to have a major impact in EB herpetiformis. Hyperkeratosis of the palms and soles often develops beginning in early childhood and can progress to confluent keratoderma of the palms and soles. These can be quite painful, and, occasionally, interference with ambulation has led to flexural contractures. Occasionally, involvement of the esophagus in EB herpetiformis, ranging from erosions to pyloric atresia,[70] has been reported. The upper respiratory tract can also be affected, including laryngeal involvement.[71] Natal teeth have been described in a few patients with EB herpetiformis.

LOCALIZED EPIDERMOLYSIS BULLOSA SIMPLEX Localized EBS is the mildest form of EB and is often referred to as the *Weber-Cockayne sub-type of EBS* (Fig. 60-5). This disease is the most common form of EB and often presents during infancy or childhood. Occasionally, it presents in early adulthood, such as when blisters are noted on the feet after marching during military service. It is speculated that there are a number of undiagnosed cases of this form of EB, as it can be mild enough to escape reporting or detection during clinical visits. Hyperhidrosis of the palms and soles is a common association. Blisters can occasionally become secondarily infected. Post-inflammatory pigmentary abnormalities occur with this variant, but milia and scarring as a rule are absent. Blistering activity usually follows areas of trauma, with hands and feet being the most common, and the scalp being the least common. Mild oral erosions are present only rarely and usually resolve with increasing age. Nail involvement is rare with this EB sub-type.

ADDITIONAL VARIANTS OF EPIDERMOLYSIS BULLOSA SIMPLEX (See Table 60-1)

Epidermolysis Bullosa Simplex of Ogna. Onset of EBS of Ogna in infancy is common with seasonal blistering (summer) on the acral areas. Small hemorrhagic and serous blisters occur primarily on the extremities. Healing occurs without

scarring. All patients described thus far have come from Norway. These patients also show a characteristic onychogryphosis of the great toenails.

Epidermolysis Bullosa Simplex Superficialis. EBS superficialis is an uncommon form of EBS that is named after the subcorneal separation that produces the blisters in this disease. Erosions and crusts, rather than intact bullae, are usually seen in these patients, who heal with post-inflammatory pigmentary changes. Despite the superficial cleavage plane, oral erosions, nail involvement, and milia have been observed in this disease.

Epidermolysis Bullosa Simplex with Mottled Pigmentation. EBS with mottled pigmentation, as its name implies, is characterized by mottled hyperpigmentation of the trunk and proximal extremities. There is blistering in a generalized distribution beginning at birth or early infancy. Blistering may improve with increasing age, and it is the pigment abnormalities that tend to progress during childhood, leading families to seek medical attention. Small, acral verrucous papules are also characteristic. Mild oral mucosal involvement may be present in infancy. This condition is distinct from the large melanocytic nevi, which can be seen in all three EB types.[72]

MOLECULAR PATHOLOGY OF EPIDERMOLYSIS BULLOSA SIMPLEX Most of the patients with EBS analyzed at the genetic level have been found to be associated with mutations of the genes coding for K5 and K14 keratins.[73] The level of separation of the skin in these patients is at the mid-basal cell, shown in Fig. 60-2A, associated with variable intermediate filament clumping. Hemidesmosomes and other BMZ structures are normal by electron microscopy. The majority of keratin gene mutations associated with EBS are dominantly inherited due to abnormalities in the multimeric assembly of keratin filaments. There is a smaller subset of patients with recessively inherited disease of varying severity.[74,75]

Mutations coding for the most conserved regions of K5 and K14 keratins, the helix boundary domains,[76] correlate with the most severe forms of EBS, such as the Dowling-Meara sub-type, which exhibits intermediate filament clumping seen by TEM. On the other hand, milder types of disease, such as the Weber-Cockayne sub-type, are associated with mutations coding for regions of K5 and K14 keratins that are less conserved. Mutations that code for a specific region of the amino terminus of K5 keratin are present in patients having EBS with mottled pigmentation.[77] Although the significance of this type of mutation and its association with pigmentary abnormalities remain unclear,[78,79] it has been suggested that the K5 keratin globular head domain is responsible for keratin filament insertion onto melanosomes.

Hemidesmosomal Epidermolysis Bullosa

Historically, EB has been subclassified according to the level of skin separation noted in biopsies of skin blisters by transmission electron microscopic analysis. Although EB has traditionally been classified into simplex, junctional, and dystrophic categories, two more rare forms of EB have been more recently described, which form a distinct level of skin separation. Hemidesmosomal EB consists of blistering skin disease with a level of separation that is intermediate between that of EBS and junctional EB (JEB). Ultrastructurally, the level of skin

Junctional	Localized	COL17A1
Dystrophic	Pasini	COL7A1
Dystrophic	Cockayne-Touraine	COL7A1
Dystrophic	Localized RDEB	COL7A1
Dystrophic	Hallopeau-Siemens	COL7A1
Variable	Kindler syndrome	KIND1
Desmosomal	Ectodermal dysplasia-skin fragility	PKP1

COL7A1 = collagen, type VII, α_1; EB = epidermolysis bullosa; ITGB = integrin β; KRT = keratin; LAMA = laminin α; LAMB = laminin β; PKP = plakophilin; PLEC = plectin; RDEB = recessive dystrophic epidermolysis bullosa.
[a]Alternatively classified as simplex.
[b]Alternatively classified as junctional.
[c]Case with type XVII collagen cytoplasmic deletion showed both junctional and hemidesmosomal levels of skin separation.[120]

separation, while intraepidermal, is localized at the inferior aspect of basal keratinocytes, at the point of insertion of keratin filaments onto the hemidesmosome (see Fig. 60-2E). Typically, small fragments of basal cell plasma membrane are present, often with electron dense hemidesmosome fragments, atop the dermal side of the skin separation.[67] Of the two diseases that form this type of separation, one is associated with muscular dystrophy; the other is associated with pyloric atresia.

EPIDERMOLYSIS BULLOSA WITH MUSCULAR DYSTROPHY EB with muscular dystrophy is a rare clinical entity that is an autosomal recessive disorder that consists of generalized blistering of the skin at birth or shortly thereafter. This is accompanied by a progressive muscular dystrophy.[80] It presents with generalized blistering similar to EBS of Koebner, clinically. These patients have been shown to harbor mutations in the gene coding for HD1/plectin.[81–83] The mutations associated with this disease produce premature termination codons that result in lack of expression of plectin. Plectin is normally expressed in a wide range of tissues, including muscle. Although the mechanism of muscular dystrophy in plectin-deficient patients is unknown, it has been observed that disorganization of muscle sarcomeres occurs in the absence of plectin. It is possible that absence of plectin's spectrin-like domain, which may normally interact with actin filaments in muscle, may be a key factor in the muscle pathology.[84]

EPIDERMOLYSIS BULLOSA WITH PYLORIC ATRESIA Patients with EB with pyloric atresia exhibit extreme mucosal and cutaneous fragility and may also have various urologic abnormalities, including hydronephrosis and nephritis. Mutations of the genes coding for the β_4 and α_6 integrins have also been associated with EB.[85–91] In this group of diseases, pyloric atresia is present. Although pyloric stenosis is relatively more common, the distinct association of pyloric atresia, a relatively rare condition, with EB makes this disease particularly unique. In these patients, hemidesmosomes are almost absent or rudimentary at best, and the level of separation is such that fragments of the basal cell plasma membrane remain adherent to the base of the blister. The skin ultrastructure in patients with $\alpha_6\beta_4$ defects is remarkably similar to the β_4 integrin knockout mice described in the section Anchoring Filaments in on-line edition; however, the mice do not show pyloric atresia. These studies illustrate well that there are limitations in the utility of animal models of EB. Most cases of this disease are quite severe and lethal in infancy due to extensive extra-cutaneous epithelial sloughing in addition to wide-

▲ **FIGURE 60-3** Widespread blistering in an infant with generalized epidermolysis bullosa simplex.

◀ **FIGURE 60-4** Characteristic blister formation on trunk and arm in patient with epidermolysis bullosa simplex herpetiformis.

▲ **FIGURE 60-5** Trauma-induced blistering from clothing in a patient with localized epidermolysis bullosa simplex.

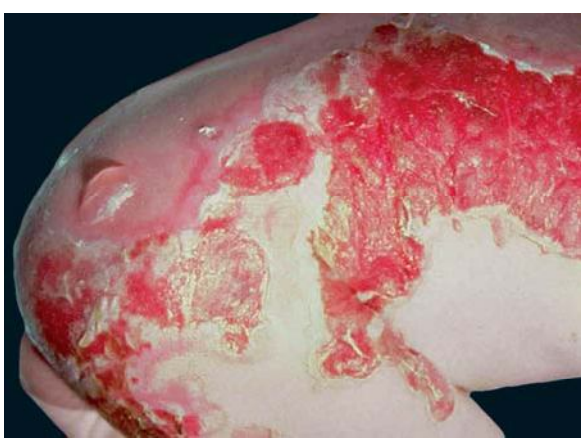
spread blistering of the skin and mucosa. Rare, nonlethal cases of this disease have been characterized, which appear to result from a partial loss of function of β_4 integrin.[92] Interestingly, nonlethal JEB can sometimes ameliorate itself through alterations in messenger RNA splicing.[93,94]

Junctional Epidermolysis Bullosa (See Table 60-1)

All patients with JEB share the common histopathologic feature of blister formation within the lamina lucida of the BMZ due to defects of anchoring filaments. This group of diseases is inherited in an autosomal recessive manner, and there is considerable variation of the individual clinical phenotypes, depending on the molecular defect. Three principal forms of JEB are most common. *Herlitz disease*, *JEB gravis*, or *lethal JEB* are each used to describe patients presenting with the most severe phenotypic disease.[17,95] It is unfortunate that this most severe sub-type of JEB is also the most common. A more indolent form of JEB is termed *mitis JEB*, and a third relatively mild form is called *generalized atrophic benign EB*.

◀ **FIGURE 60-7** Periorificial erosions and hypertrophic granulation tissue in a patient with junctional epidermolysis bullosa mitis.

JUNCTIONAL EPIDERMOLYSIS BULLOSA GRAVIS Lethal JEB or Herlitz JEB patients typically do not survive infancy, and death rates are estimated at 40 percent in the first year of life. Of those that survive infancy, most die before 5 years of age. This disease is characterized by generalized and often extensive blistering at birth (Fig. 60-6). Later during infancy, a distinctive periorificial granulation tissue manifests. This can occur around the mouth, eyes, and nares most commonly, but also can be present in the scalp, around the ears, and, less frequently, in other locations besides the head and neck (see eFig. 60-6.1 in on-line edition). This hypertrophic granulation tissue can also occur in nonlethal sub-types. Nails are usually severely affected and often are lost during infancy. When nails are still present, they are usually dystrophic and often associated with hypertrophic granulation tissue. Dental defects are present in this disease, characterized by pitting of the tooth enamel. Oropharyngeal mucosal erosions are usually present and may be widespread. Erosions of all stratified squamous epithelial tissues, including nasal, conjunctival, esophageal, tracheal, laryngeal, rectal, and urethral mucosa, can be affected. Associated systemic findings in severe cases are important factors in the lethality of this disease. Involvement of the large airways, including tracheolaryngeal stenosis or obstruction, is commonly associated with Herlitz disease, and hoarseness in early infancy is an ominous sign. There is a characteristic failure to thrive and growth retardation in this disease, often with a mixed anemia. Sepsis is a common and often lethal complication.



◀ **FIGURE 60-6** Widespread blistering at birth in a patient with Herlitz junctional epidermolysis bullosa.

JUNCTIONAL EPIDERMOLYSIS BULLOSA MITIS Sometimes, patients initially presenting with a Herlitz-like phenotype will survive infancy and clinically improve with age. These patients eventually prove to have a severity of blistering and oral erosions less than the lethal form. In particular, a lack of significant hoarseness is regarded as a favorable prognostic sign, indicative of less severe internal disease manifestations. Scalp and nail lesions, as well as periorificial non-healing erosions, are among the most common findings in these patients during childhood (Fig. 60-7). Despite the lack of lethality in infancy, these patients, nonetheless, can have severe epithelial adhesion abnormalities, and tracheostomies or gastrostomy tubes may help in patient survival (see Fig. 60-7). The nonlethal status of these patients distinguishes them from the Herlitz group, and the terms *nonlethal JEB* or *JEB mitis* have been used to describe these patients. They are much less common than Herlitz EB patients. There are other rare variants of nonlethal JEB that present with localized junctional blistering of the extremities or intertriginous areas.

GENERALIZED ATROPHIC BENIGN EPIDERMOLYSIS BULLOSA Generalized atrophic benign EB also presents at birth with generalized cutaneous involvement.[96] These patients have features that distinguish them from Herlitz and mitis/nonlethal sub-types described above in Junctional Epidermolysis Bullosa Gravis and

▲ **FIGURE 60-8** Loss of nails and skin atrophy in a patient with generalized atrophic benign epidermolysis bullosa.

Junctional Epidermolysis Bullosa Mitis. Despite the widespread cutaneous blistering, there is a relative paucity of oral erosions. Although enamel pitting is present, resulting in extensive dental caries, and nail dystrophy can often be severe (Fig. 60-8), there is little other extracutaneous involvement noted in these patients. The blisters in these patients, which heal with a characteristic atrophic scarring, are debilitating and can be widespread, but nonetheless, these patients generally have a normal lifespan. Blistering improves with age, growth is normal, and anemia is rarely seen. Some patients with this disease have undergone normal, uncomplicated pregnancies and deliveries. One peculiar characteristic of these patients is a progressive alopecia of the scalp and terminal hairs elsewhere in the body (see eFig. 60-8.1 in online edition). The hair loss starts to become severe after the onset of puberty, and although patchy hair loss associated with atrophic scarring has been described, often the alopecia is quite diffuse and scarring is subtle or non-existent.

LOCALIZED JUNCTIONAL EPIDERMOLYSIS BULLOSA A very rare sub-type of JEB is the localized variant, also known as *minima JEB*. These patients generally show mild disease that can be accentuated in localized areas, most often the hands, feet, and pretibial regions. Nails can sometimes be shed or become dystrophic, and enamel pitting can occur. Oral or nasal erosions can also occur; however, there is an absence of any internal involvement. These patients generally have a favorable prognosis and a normal lifespan.

MOLECULAR PATHOLOGY OF JUNCTIONAL EPIDERMOLYSIS BULLOSA JEB can be associated with mutations of the genes coding for either the α_3, β_3, or γ_2 subunits of laminin-332 (i.e., LAMA3, LAMB3, LAMG2, respectively).[97–102] Absence of any of the three chains results in a lack of trimeric laminin-332 assembly and secretion, which results in a similar blistering phenotype. Patients with mutations of genes coding for the β_3 or γ_2 laminin subunits will still show normal expression of laminin-311, which contains α_3, β_1, and γ_1 chains. Therefore, positive linear BMZ staining of JEB skin for α_3 chain on IDIF with absent expression of the other chains is an indication of either a β_3 or γ_2 chain defect. Conversely, absence of α_3 staining on IDIF can be indicative of a mutation of the α_3 gene. About 80 percent of laminin-332 mutations can be traced to one of two recurrent nonsense mutations in the LAMB3 gene, making prenatal testing for laminin-332 lesions easier than other EB candidate genes.[103] In the letalis patients, all of the mutations so far detected have been those producing premature termination codons, resulting in absence of expression of laminin-332. Although Herlitz cases generally show a complete lack of expression of laminin-332, nonlethal/mitis patients often show reduced expression of laminin-332. This is due to expression of a molecule with deletions or missense mutations, resulting in partial loss of laminin-332 function. This can lead to cases clinically classified as mitis or generalized atrophic benign JEB (GABEB).[97,104–108] In some cases, spontaneous amelioration of blistering in severe JEB cases has taken place that has been associated with genetic mechanisms, which result in the re-expression of laminin-332.[94]

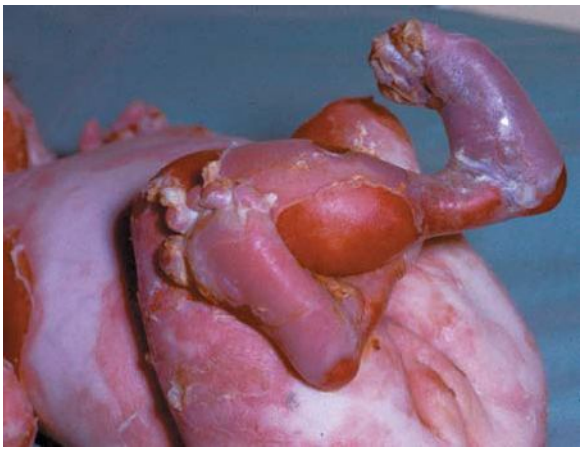
In the JEB variant, GABEB, blistering occurs in the lamina lucida region, and abnormalities of hemidesmosomes/anchoring filaments are usually present (see Fig. 60-2H). Although laminin-332 mutations underlie a subset of GABEB patients, the majority of these patients have abnormalities of the hemidesmosomal protein type XVII collagen (also known as BP180 or BPAG2).[109] A number of mutations of the gene coding for type XVII collagen[110–119] have been described in GABEB patients, including premature termination codon mutations, missense mutations, splice site mutations, truncations, and a glycine substitution mutation. Although intralaminin lucida/junctional skin separation has been shown in all patients with this disease, one patient was described with a cytoplasmic deletion of type XVII collagen who had both hemidesmosomal as well as junctional skin separation.[120] Localized JEB has been shown to be associated with COL17A1 mutations.[115] Of interest, one mosaic GABEB patient was identified who demonstrated well-defined areas of blistering associated with absence of type XVII collagen expression as well as areas of nonblistering skin associated with normal type XVII collagen expression. Careful analysis of the patient's keratinocytes revealed reversion of one of the two alleles of the mutation (revertant mosaicism), most likely due to a mitotic gene conversion involving non-reciprocal exchange of parental allele DNA.[121] This has also been demonstrated in another case.[122] It is possible that this phenomenon of mutational rescue of genes affecting recessive cases of EB is more widespread than currently reported, and more careful examination of involved and uninvolved regions of EB skin undoubtedly will reveal more cases. Understanding how EB can undergo spontaneous molecular correction in these cases could help in the design of future exogenously based molecular therapies.

Dystrophic Epidermolysis Bullosa (See Table 60-1)

DEB, also termed *dermolytic EB*, is characterized by blisters that heal with scarring and milium formation. DEB can be inherited either in an autosomal recessive or dominant fashion. Regardless of the mode of inheritance, DEB is derived from defects of the ultrastructural entity known as the *anchoring fibril*, which results in sublamina densa separation. There are four primary sub-types of DEB but several additional rare forms also exist. The main sub-types are differentiated by clinical criteria and include dominant DEB of Cockayne-Touraine, dominant DEB of the albopapuloid or Pasini variant, localized recessive DEB (RDEB), and generalized RDEB.

DOMINANT DYSTROPHIC EPIDERMOLYSIS BULLOSA The Cockayne-Touraine subtype of dominant DEB can present at birth, but, occasionally, it is not appreciated until childhood. Although generalized blistering can sometimes take place, especially early in life, the blistering usually becomes localized to repetitively traumatized areas such as knees, sacrum, and acral surfaces (Fig. 60-9). These areas show a characteristic scarred, dystrophic appearance. Often the scarring is hypertrophic. Milia are common accompanying features of the healing process in

▲ **FIGURE 60-9** Localized trauma-induced blistering with secondary milia in a patient with dominant dystrophic epidermolysis bullosa.



◀ **FIGURE 60-10** Widespread blistering with localized absence of skin at birth in a patient with recessive dystrophic epidermolysis bullosa.

these patients. Nail dystrophy or nail loss with atrophic scarring of the distal digits are common. Oral lesions are not common, and teeth are usually unaffected. These patients have a good prognosis and a normal lifespan.

The Pasini sub-type of DEB presents at birth with a generally more severe and widespread blistering phenotype compared with the Cockayne-Touraine variant. Blisters in the Pasini sub-type heal with scarring plaques and milia in a fashion similar to other DEB sub-types. In addition, this disease is characterized by the spontaneous appearance of distinctive, scar-like, flesh-colored papules on the trunk. These albopapuloid lesions are characteristic of the Pasini subtype but not pathognomonic, as these lesions can also be seen in other EB subtypes. As the patients get older, the generalized blistering may eventually localize to the extremities. Patients often show dystrophic or absent nails. Oral erosions can often be present, but usually are not extensive, and enamel defects can be seen in some patients.

RECESSIVE DYSTROPHIC EPIDERMOLYSIS BULLOSA RDEB can be quite variable in its severity. Although the severe sub-type is the most common, a localized form can occasionally be seen, which has been termed *RDEB mitis*. Similar to the Cockayne-Touraine DEB, localized RDEB is usually confined to repetitively traumatized skin surfaces, most often in an acral distribution. Scarring and milium formation accompany the healing of blisters. Mucosal involvement, if present, is mild.

Severe RDEB, also known as the *Hallopeau-Siemens* (HS) variant, is a devastating disease (Fig. 60-10). This disease presents with generalized blistering at birth. Occasionally, there is extensive denudation of an entire region of skin at birth, often involving one of the limbs. This congenital absence of skin is sometimes termed *Bart syndrome*. Healing and blistering cycles occurring during infancy can lead to progressive ulcerations and scarring that can become quite extensive (see eFig. 60-10.1 in on-line edition). Pseudosyndactyly resulting from a closure of the digits in a "mitten" of skin is extremely common in this disease (see Fig. 60-2J). Scarring can lead to flexion contracture of the hands as well as the limbs. In contrast to the severe JEB patients, these patients do not show significant periorificial involvement. Instead, the scalp is the most commonly affected area on the head and neck of these patients.

The oropharynx can be extensively involved in both dominant and RDEB (Fig. 60-11), with generalized erosions evolving into a scarring that limits the movement of the tongue and narrows the opening of the oral cavity. The teeth can show significant enamel pitting, and caries can be extensive, leading to loss of teeth. Involvement of the trachea or larynx can lead to a narrowing of the airway that could require intervention with a tracheostomy. Mucosal erosions of the esophagus can lead to stricture formation and webbing. The combination of oral lesions, dental caries, esophageal strictures, and increased caloric needs from extensive wound healing can lead these patients toward malnutrition and growth retardation. These patients usually have problems with anemia and may show a deficiency of iron absorption.

In the more distant past, most severe RDEB patients died in infancy of sepsis and other complications of extensive blistering. More recently, with improved nutritional and wound care support, these patients usually can survive into their teens or into adulthood. However, after puberty, another devastating complication, squamous cell carcinoma (SCC), can, and often does, appear. It is estimated that 50 percent to 80 percent of HS-RDEB patients eventually develop these carcinomas, and many of these die of metastatic disease. RDEB-associated carcinomas are extremely aggressive, with strong tendencies for invasion and metastasis.

MOLECULAR PATHOLOGY OF DYSTROPHIC EPIDERMOLYSIS BULLOSA Abnormalities of anchoring fibrils in DEB patients range from subtle changes in some patients with dominant disease, to absence of anchoring fibrils in patients with the severe recessive form, and a sublamina densa plane of blister cleavage is also present (see Fig. 60-2I). These observations correlate with IDIF microscopic analysis of DEB patients, which demonstrates varying degrees of linear basement membrane staining in dominant patients and totally absent staining in severe recessive patients. In some patients, there is a cytoplasmic retention of type VII collagen that can be demonstrated in patient biopsy sections and analysis of patient keratinocytes.[123]

▲ **FIGURE 60-11** Oral erosions in a patient with dominant dystrophic epidermolysis bullosa.

DEB has been shown to be associated in all cases thus far with mutations of the gene coding for type VII collagen (COL7A1). In the recessive forms, mutations usually cause premature termination codons that result in lack of type VII collagen in tissue. It is known that messenger RNAs bearing premature stop codons show accelerated turnover.[124] In addition, truncated proteins that are not secreted or not assembled into anchoring fibrils may also show accelerated turnover. Either or both of these mechanisms can explain the lack of detectable type VII collagen in the tissue of individuals with severe RDEB associated with mutations that produce premature termination codons.[60,125,126]

Generally, COL7A1 mutations that do not cause premature termination codons produce less severe disease.[60,127–135] For example, mutations that produce glycine substitutions of the triple helical region interfere with triple helical assembly of the type VII collagen molecule. These types of mutations are present in many patients with milder dominant forms of this disease. In these patients, type VII collagen molecules may not be able to assume the proper conformation needed to polymerize into anchoring fibrils. Other COL7A1 mutations have been shown to be associated with impaired secretion of type VII collagen, resulting in intracellular accumulation of this molecule.[133,136–138] In one study, DEB patient mutations that involve the area of the gene coding for the type VII collagen NC-2 domain were shown to interfere with NC-2 processing and the assembly of anchoring fibrils.[139]

Other Inherited Skin Disorders Related to Epidermolysis Bullosa

New advances in our understanding of the molecular pathology of the skin have brought to light the underlying pathophysiology of two diseases that are related to EB—Kindler syndrome and ectodermal dysplasia/skin fragility syndrome.

KINDLER SYNDROME Kindler syndrome was first described by Theresa Kindler in 1954.[140] It is characterized by EB-like, trauma-induced blistering at birth and during infancy, with atrophic changes during healing reminiscent of junctional or dystrophic EB.[141–147] However, in late childhood, the blistering usually subsides and gives way to a progressive poikiloderma that distributes to sun-exposed areas. The poikiloderma may show areas of atrophy and hyperkeratosis, as well as hypopigmentation, hyperpigmentation, and telangiectasias. These patients often show photosensitivity. Nail changes and webbing of the toes and fingers are also sometimes present. Internal complications include oral inflammation, esophageal or ureteral strictures, and ectropion. Ultrastructurally, these patients show reduplication of the basement membrane, which is the most consistent feature seen. Although there is often a sublamina densa split with anchoring fibril abnormalities, sometimes lamina lucida or intraepidermal separation can be seen, associated with the blistering phenotype. Molecular investigation of this disease led to the discovery of a new epidermal protein, kindlin-1, which shows decreased expression by immunofluorescent microscopy in this disease.[148–151] Kindlin-1 appears to have some homology to signaling proteins such as talin, which suggests a signaling function, but its role in Kindler syndrome remains unclear. A number of mutations of the gene coding for kindlin-1, KIND1, have been described.[148,149,151–156] These include nonsense, frameshift, and splice site mutations that underlie the observed decreased kindlin-1 expression in affected skin. Why the disease evolves from a blistering to a poikilodermatous phenotype and the exact function of kindlin-1 in epidermal homeostasis remain to be fully elucidated.

ECTODERMAL DYSPLASIA-SKIN FRAGILITY SYNDROME Ectodermal dysplasia-skin fragility syndrome is a rare disorder characterized by skin erosions, skin fragility, and peeling beginning at birth or infancy.[157] Alopecia is also very common, as are palmoplantar keratoderma, painful fissures, and nail dystrophy. Patients may sometimes demonstrate failure to thrive, cheilitis, hypohidrosis, and pruritus as well. The underlying molecular defect has been shown to be loss of function of the desmosomal protein plakophilin 1.[158] Plakophilin is expressed mainly in suprabasilar keratinocytes and outer root sheath cells. Microscopic findings in this disease usually show intraepidermal acantholysis located in the areas where plakophilin 1 is normally expressed. The molecular defect involves loss of function mutations in the PKP1 gene coding for plakophilin 1.[159–164]

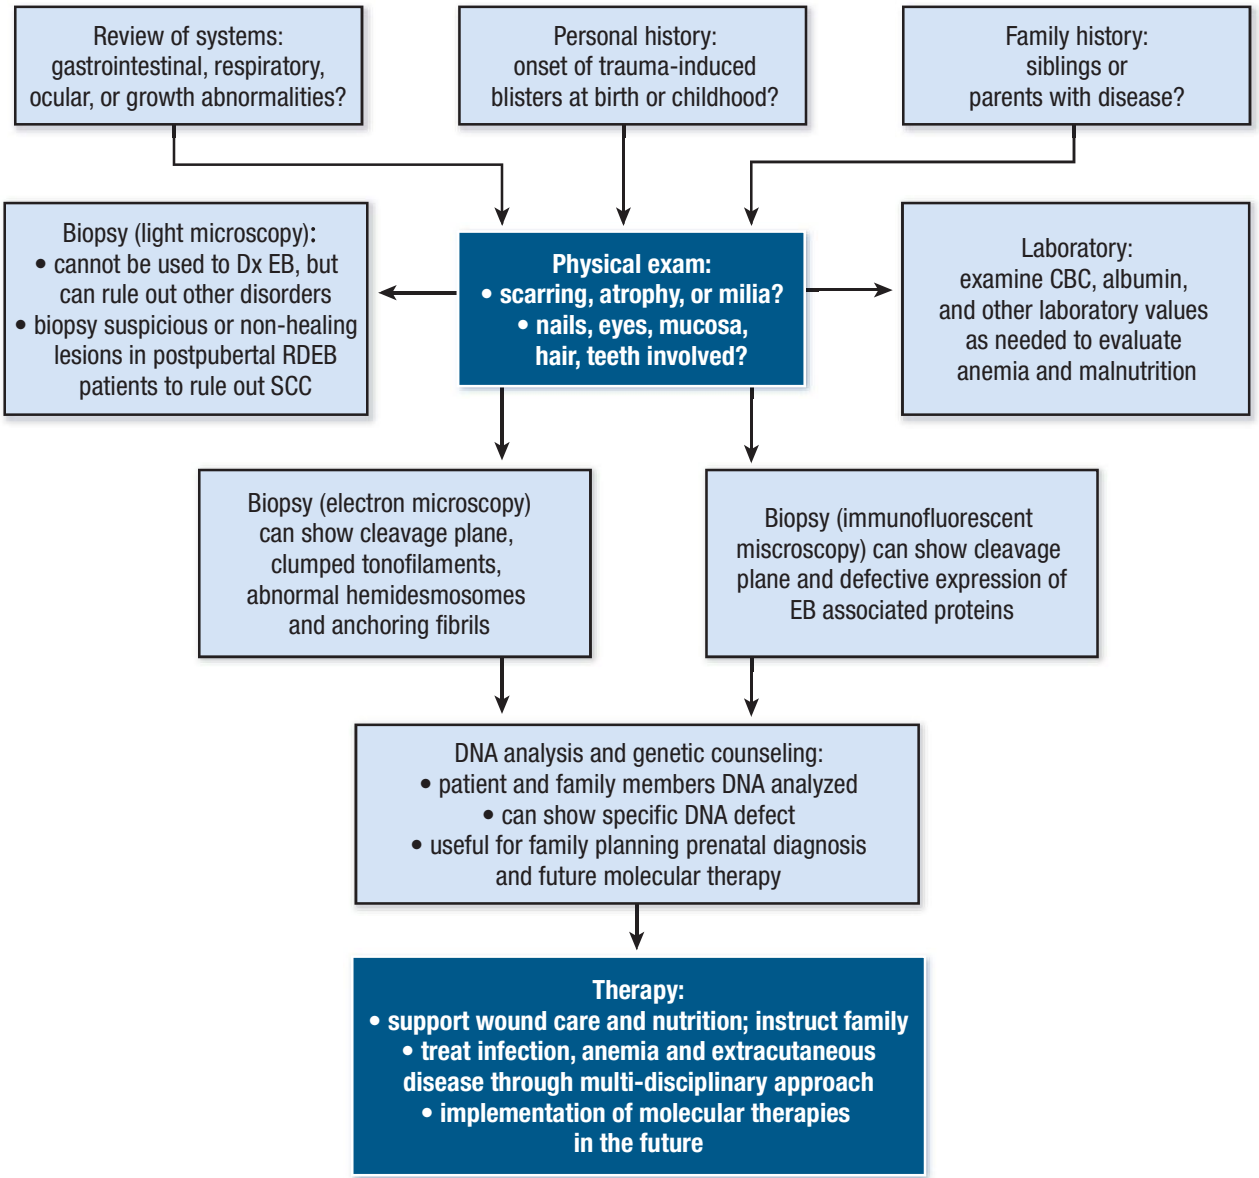
DIAGNOSIS

The first step toward making the diagnosis of EB begins with a thorough history and physical examination (Fig. 60-12). Useful historical information includes the age of onset of blistering and the presence of blistering in other family members. A review of gastrointestinal (GI), respiratory, ocular, dental, and genitourinary systems is important as is evaluation of general growth and development. Physical examination requires not only a complete skin examination, but a thorough evaluation of mucosal tissues, hair, nails, and teeth. Laboratory measurements of importance in the initial visit include evaluation for anemia and for measures of nutrition, such as serum albumin.

Skin biopsy is another important diagnostic step. Routine histologic analysis cannot be used to diagnose EB but can be useful for excluding other causes of blistering. The dermal-epidermal BMZ is simply too small to be visualized by light microscopy. To differentiate levels of BMZ separation in skin biopsies, TEM and/or IDIF microscopy must be used. The interior of blisters rapidly reepithelialize, which can obscure correct determination of blister levels. For this reason, it is critical to biopsy a blister that is as fresh as possible. One way to ensure a fresh blister is for the clinician to induce it in the office. This can be accomplished by gently rotating a pencil eraser over an intact area of patient's skin until separation of the epidermis from the dermis can be observed.

TEM has been regarded for many years as the gold standard for determining the level of blistering in EB subtypes. In addition to determining the level of blistering, ultrastructural entities can also be analyzed by TEM for characteristic alterations. For example, clumping of keratin intermediate filaments in basal keratinocyte cytoplasm is a pathognomonic finding for Dowling-Meara EBS. Rudimentary hemidesmosomes can be an important clue to the diagnosis of JEB. Absent or altered anchoring fibrils often occur in DEB subtypes, especially the recessive forms.

IDIF microscopy can provide additional information on the level of blistering as well as important clues to the underlying molecular defects. In this technique, a panel of antibodies against known BMZ antigens is applied to frozen sections of blistered patient skin. The localization of the antigens to the epidermal or dermal portion of the blister indicates the level of skin separation in the BMZ. In EBS samples, for example, intracellular hemidesmosomal components, such as BP230, and a lamina densa protein, such as type IV collagen, would each localize to the floor of the blister. In JEB cases, BP230 would localize to the roof of the blister, whereas



▲ FIGURE 60-12 Approach to epidermolysis bullosa (EB) patients. A complete history, including family history and review of systems, is essential. Physical examination can provide important clues, and laboratory values can help identify associated anemia and malnutrition. Electron microscopy and/or indirect immunofluorescence microscopy is required for diagnosis. DNA analysis is helpful for determining prognosis and family planning. Therapy is mainly supportive. Teaching and working with nursing staff and especially families is critical, as is interdisciplinary interactions with other specialties in the treatment of extra-cutaneous complications. CBC = complete blood cell count; Dx = diagnosis; RDEB = recessive dystrophic epidermolysis bullosa; SCC = squamous cell carcinoma.

type IV collagen would localize to the floor. In DEB, type VII collagen and BP230 would localize to the roof of the blister. The specific absence or presence of staining with a particular antibody in frozen sections of intact portions of patient skin gives important clues to the specific molecular defect. Samples that lack staining with antibodies specific to laminin-332 would further support a JEB diagnosis, whereas a lack of staining for type VII collagen would support a DEB diagnosis. Absence of staining for BP180 would support a GABEB diagnosis.

Gene mutation analysis has revolutionized our understanding of the EB family of diseases. Concurrent advances in our knowledge of the biochemical structure and supramolecular assembly of BMZ proteins have both facilitated and complemented the molecular biology studies. Despite these advances, a complete correlation of molecular and clinical phenotypes has not yet been achieved. Thus, EB patient diagnosis requires both clinical and molecular information. Blood samples or buccal swabs are taken from the patient as well as the parents and siblings for genetic analysis.

Differential Diagnosis (See Box 60-1)

Genetic Counseling

DNA mutation analyses can be extremely helpful to EB patients. The prognostic benefit to the patient can often be highly significant. For example, RDEB cases may have equivalent blistering activity compared with the more severe dominant cases, but their risk of invasive SCC is much greater. Through DNA diagnosis, these two groups can be distinguished, thereby identifying patients potentially at risk for invasive SCC.

Prenatal diagnosis of EB in affected families can be an extremely accurate technique, especially if the original pro-

Box 60-1

Differential Diagnosis of Epidermolysis Bullosa

Most Likely

- Pompholyx
- Insect bites
- Friction blisters
- Thermal burns
- Bullous impetigo
- Bullous congenital ichthyosiform erythroderma (neonate)
- Aplasia cutis (neonate)

Consider

- Chronic bullous dermatosis of childhood (linear immunoglobulin A disease)
- Bullous pemphigoid
- Epidermolysis bullosa acquisita
- Bullous systemic lupus erythematosus
- Cicatricial pemphigoid
- Pemphigus vulgaris

Always Rule Out

- Stevens-Johnson syndrome
- Toxic epidermal necrolysis

band has previously had mutational analysis or identification of the defective gene. Fetal skin biopsies and fetoscopy with their increased risk of pregnancy loss can now be avoided by analysis of either chorionic villus sampling as early as 8 to 10 weeks[165] or amniocentesis in the second trimester.[166] The development of highly informative intragenic and flanking polymorphic DNA markers in EB candidate genes together with rapid screening of genetic "hotspots" makes genetic screening of at-risk pregnancies a viable option.[3,103,167] Coupling of the technique of in vitro fertilization with EB prenatal diagnosis, preimplantation diagnosis has now been successfully performed for EB cases.[159,165,168] Another promising area of prenatal diagnosis with potential future applications to EB is the detection and analysis of fetal cells in the maternal circulation.[169]

TREATMENT

Therapy for EB is by necessity supportive, as currently available therapies cannot correct the underlying molecular defect. The regimen is tailored to the severity and extent of skin and systemic involvement and usually entails a combination of wound management, infection control, surgical management as needed, and nutritional support. Skin care and supportive care for other organ systems in certain EB sub-types is most optimally coordinated through a multidisciplinary approach.[170,171] Comprehensive topical therapy is a mainstay of treatment in EB, with avoidance of trauma as a primary goal. Wound healing is impaired by endogenous factors, including foreign bodies, bacteria, nutritional deficiencies, anemia, and repeated trauma. Therefore, optimizing wound healing in EB patients involves control of all of these factors.[172]

Supportive Skin Care

Extensive areas of denuded skin can result in the loss of the barrier provided by the stratum corneum. Subsequent microbial penetration can result in the accumulation of serum and moisture that further enhances bacterial propagation. The above factors combined with immunosuppressive therapy facilitate development of infections. Prevention of infection is obviously the preferred strategy.

A modified Dakin's solution (0.025 percent weight per volume sodium hypochlorite) can be helpful in reducing the bacterial load in patient skin.[173,174] Soaking wounds in this solution for 20 minutes before dressing changes also helps to free adherent bandages that have dried onto the wound bed. After soaking, wounds can be dressed with mupirocin or other topical antibiotics and covered with semiocclusive nonadhesive dressings. Tape causes further blistering and peeling of the skin; thus it is essential to use self-adhering (clinging) gauze to hold non-adherent dressings in place.

For patients with most sub-types of EBS, such as Koebner and Weber-Cockayne EBS, avoiding exposure to heat is key to controlling blister formation. Advising patients to use soft, well-ventilated shoes is also recommended. Herlitz JEB patients, lacking functional laminin-332, an extracellular matrix protein shown to be involved in keratinocyte adhesion and migration, may have especially difficult problems with wound healing. In JEB patients with chronic hypertrophic granulation tissue in the periorificial regions of the face, keratinocyte autografts have been used.[175,176] For DEB patients, use of finger splinting or diligent hand wrapping and appropriate hand protection against trauma are helpful, especially after hand surgery (see Surgical Treatment).

Treatment of Infection

Management of skin infections is a critical part of EB patient care. Large areas of denuded skin, a common finding in EB patients, provides an inadequate barrier to microbial penetration. Patients with severe EB sub-types, such as RDEB, may also have immunologic abnormalities, including decreased lymphocyte production due to poor nutritional status that lower a patient's resistance to infection. *Staphylococcus aureus* and *Streptococcus pyogenes* are common infectious agents. Gram-negative infections with *Pseudomonas aeruginosa* can also occur. Sepsis is a common cause of death in JEB letalis patients. Skin cultures and the use of the appropriate systemic antibiotics are indicated for wound infection. To prevent infections in chronic wounds, a regimen entailing regular whirlpool therapy followed by topical antibiotics is the preferred strategy. Rotation of topical antibiotics is also a helpful way to combat resistant bacteria.

Surgical Treatment

Among the EB patient population, those with the severe HS-RDEB variant are generally the most in need of surgical intevention.[177] Mitten pseudosyndactyly in these patients can be surgically released; however, this procedure may have to be repeated periodically due to the strong tendency of this condition to recur.[178–181] Splinting after surgery is essential to reducing recurrence of hand deformities. Surgery may also be used to correct limb, perioral, and perineal contracture deformities; but, unfortunately, recurrence is common.[177,182,183] Extra care must be taken to minimize trauma to the oral mucosa in EB patients during intubation.[184,185]

In the case of tissue-engineered skin, application of allogeneic skin equivalents has recently demonstrated some promise in wound healing and improvement of quality of life[186] and thus represents an area of future investigation. Although long-term benefit or persistence of allografted cells has not been demonstrated, this therapy nonetheless appears to be a helpful short-term therapy to help chronic EB wounds to heal.

Treatment of Tumors

SCC often arises after puberty in patients with RDEB.[187,188] SCC may arise in multiple primary sites, especially in nonhealing areas. Careful surveillance of non-healing areas is of utmost importance because patients often die from metastatic disease. Surgical excision using either Mohs or non-Mohs ap-

proaches is an important first-line modality, with radiation therapy limited by poor tumor response and impaired site healing.[189] Isotretinoin has been used for RDEB patients for chemoprevention of SCC. Although it appears well tolerated, it is not clear whether it can increase the overall survival rate of these patients.[190]

Care for Extra-Cutaneous Involvement

GASTROINTESTINAL MANAGEMENT Esophageal lesions are often the most disabling complication found in RDEB and JEB of both the Herlitz and non-Herlitz varieties.[191–194] Esophageal strictures usually respond to dilatation; however, recurrence of strictures after dilation is common.[195] Colonic interposition has proved effective in advanced cases. Gastrostomy tube insertion has been effective in providing nutrition to individuals with esophageal strictures.[193] Increased fluid and fiber intake and stool softeners may also be of value in EB patients who suffer from constipation.

EYE LESIONS EBS patients, particularly those with the Dowling-Meara subtype, can experience recurrent inflammation of the eyelid, with bullous lesions in the conjunctivae. JEB and RDEB patients can experience corneal ulcerations with scarring, obliteration of tear ducts, and eyelid lesions.[196] Cicatricial conjunctivitis can also occur in RDEB patients. Corneal erosions are treated supportively with application of antibiotic ointments and use of cycloplegic agents to reduce ciliary spasms and provide comfort. Moisture chambers and ocular lubricants are also commonly used. Severely affected upper eyelids may be surgically managed with full-thickness skin grafting. Complete correction of any eye disorder in EB patients is difficult to achieve. Proper management of eye lesions in EB patients must include the assistance of an ophthalmologist to prevent serious visual compromise.[197,198]

OROPHARYNGEAL LESIONS Good dental hygiene is essential for EB patients, and regular visits to the dentist are especially important. Enamel defects in JEB and DEB patients often lead to dental carries.[199,200] The softest brush available should be used for regular cleansing. Oral mucosal blistering may also accompany forms of JEB and DEB. Normal saline rinses are effective for gentle cleaning of the mucosal surfaces. Mouthwashes containing alcohol or other harsh agents should be avoided. Erosions and scarring involving the trachea and larynx with resultant narrowing of the airway can occur both in JEB and DEB patients and should be evaluated by gentle endoscopy with an otolaryngologist or other surgical specialist. In patients with airway involvement, there is danger of pulmonary aspiration.[182]

NUTRITION AND ANEMIA Nutritional assessment and support can be critical in EB patients[201] for several reasons. Extensive cutaneous injury is associated with marked alterations in hemodynamic and metabolic responses, with increased caloric and protein requirements. Oropharyngeal as well as GI lesions provide the greatest overall threat to nutritional well-being. These include oral blistering, abnormal esophageal motility, strictures, dysphagia, diarrhea, malabsorption, and dental problems. Nutritional assessment must take into account the preceding factors to develop a supplemental regimen to replenish nutritional deficiencies. Patients are often unable to increase their food intake to balance this increased caloric need. For example, hypoplastic enamel formation in certain sub-types of EB such as GABEB may lead to tooth decay, mucosal blistering, and oral candidiasis. All of these potential complications may compromise a patient's ability to eat. Extensive internal mucosal disadhesion in the GI tract may cause abnormal GI motility, strictures, and diarrhea, complications that may lead to malabsorption of iron and other nutrients. Anemia of chronic disease can certainly affect all severe EB sub-types. RDEB patients often show a particularly severe defect of iron absorption from the GI tract. Often in these patients, an iron-deficient anemia can develop, which is not responsive to oral supplementation. For these patients, parenteral iron can be helpful. Furthermore, if a lack of a reticulocyte response to iron supplementation is seen in iron-deficient patients, it is helpful to assess the erythropoietin level and to treat with recombinant erythropoietin, if necessary.[202] Transfusion is also useful in the treatment of anemia in EB, especially when symptoms require a rapid correction.

TREATMENT OF PSYCHOLOGICAL ASPECTS OF EPIDERMOLYSIS BULLOSA Patients with EB, especially the severe sub-types, can be plagued with chronic pain and debilitation.[203] Although many, despite extremely adverse conditions, seem to find a way to maintain a surprisingly positive outlook on life, others lapse into depression.[204] Severe EB patients can also create stress for their families and loved ones.[205,206] Thus, it is important to identify the warning signs of depression when they arise and to work in a multi-disciplinary approach with psychiatrists and clinical psychologists, as needed. Supportive psychotherapy and patient support group meetings can help patients and their families in this regard. An additional source of support for patients and families includes several important lay person organizations that assist with patient education and support, including the Dystrophic Epidermolysis Bullosa Research Association of America (http://www.debra.org) and the Epidermolysis Bullosa Medical Research Foundation (http://www.ebkids.org).

Systemic Therapies

Systemic therapies are not effective in ameliorating the fundamental blistering tendencies in EB patients. Tetracycline and phenytoin have been used in the past for EB but are not currently indicated treatment.[207,208] Corticosteroids, either topical or systemic, have no beneficial, long-term use in inherited EB.

Future Directions In Molecular Therapy

A number of pre-clinical models have facilitated the study and development of therapy for EB. Some of these models use mouse genetic approaches to produce entirely murine tissue models.[209] These include transgenic mouse models with skin-targeted expression of transdominant molecules,[210] such as inducible dominant-negative mutations in basal cell keratins in models of EBS.[211] Murine knockout models have also been used, including knockout of basal keratin genes in a model of recessive EBS and of the α_6 and β_4 integrins, laminin-332, and type VII collagen.[212,213] These targeted gene disruptions in mice have accurately recapitulated the blistering phenotype of the corresponding human disorders. These murine genetic models have been of great use in clarifying our understanding of the pathogenesis of this group of disorders and in providing disease models for development of potential future therapies. Other animal models have also been shown to have the potential to study EB pathophysiology and therapy in a pre-clinical

setting. Canine, equine, and feline forms of a number of sub-types of EB show promise as pre-clinical models of molecular therapy.[214–220]

In addition to such pure animal models, human skin/mouse chimeras have been generated in an attempt to produce true human tissue models of EB. These chimeras have either used full-thickness grafting of EB patient skin or epidermis regenerated on skin composites and sheets from EB keratinocytes grown in culture.[221] Immune-deficient severe combined immune deficiency and nude mice readily accept such xenografts and the grafted EB skin retains the clinical and molecular characteristics of the patient donor. This immunodeficient mouse models can be extended to study injections of human cells or proteins as well. This approach has been reported for RDEB due to mutations in type VII collagen and for benign JEB due to mutations in type XVII collagen. Because human epidermis differs dramatically from mouse epidermis in tissue architecture, these in vivo models of human tissue in EB may be of special use in development of models for gene therapy of these disorders.

Future potential therapies for EB include protein and gene therapy. In the former case, the missing or defective protein is produced by recombinant methods and applied or injected directly to intact or blistered skin. Recent studies of type VII collagen protein transfer into RDEB-derived skin equivalents has showed successful incorporation of this molecule into anchoring fibrils combined with clinical improvement of skin separation. Type VII collagen has a longer in vivo half-life than most molecules. This suggests that protein application or injection could take place at extended intervals, perhaps greater than 3 months, as persistence of exogenous type VII collagen protein was detected in animal models for at least this long. In the case of gene therapy, delivery of genes targeted to restore normal protein expression is the goal.[222] Successful corrective gene delivery has recently been achieved in human EB tissue in the immune-deficient model system described below for both laminin-332 and Type XVII collagen.[223,224] Thus, genetic therapies may be of significant use in the future. More recently, both viral and nonviral methods of gene transfer have demonstrated successful expression of type VII collagen in RDEB skin equivalents on immunodeficient mice[225–228] as well as in a canine animal model.[219] Genomic DNA therapeutic approaches have also been studied in EB keratinocytes with some success, but still at the in vitro stage.[229,230] Dermal fibroblasts have long been appreciated to be a main contributor of type VII collagen to the dermal-epidermal basement membrane.[231] Recently, approaches that inject type VII collagen-expressing fibroblasts have proved successful in restoring type VII collagen expression and reversing the blistering phenotype in RDEB skin equivalents on immunodeficient mice.[226,232] These studies suggest that molecular therapy of EB can produce durable and effective remission of blistering in vivo, which leads to a way toward future clinical applications.

Arthur Z. Eisen

COLLAGEN

Structure

The closely related proteins of the collagen family are the main fibrillar components of the connective tissues and the major extracellular proteins of the human body.[1–4] The physiologic role of collagen fibers in the skin is to provide tensile properties that allow the skin to serve as a protective organ against external trauma. In human skin, collagen fibers form the bulk of the extracellular matrix and comprise approximately 80 percent of the dry weight of the dermis. The bulk of collagen in dermis is deposited as large bundles of regularly oriented fibers composed of fibrils that are aligned in a parallel manner, which results in a pattern of cross-striations that can be visualized by electron microscopy (Fig. 61-1). The most prominent cross-striations appear as repeating bands spaced approximately 70 nm apart.

The prototype of the collagens is type I collagen, the most abundant collagen in the dermis and in most other connective tissues (Fig. 61-2). The type I collagen molecule has an approximate molecular mass of 290 kd and is composed of three polypeptide chains, each approximately 94 kd. These three polypeptides, known as the *α chains*, are coiled around each other much like strands of rope, so that the collagen monomer has a triple-helical structure. This conformation gives the molecule a rigid, rod-like shape with approximate dimensions of 1.5 × 300 nm (see Fig. 61-2).

The special structure of the collagen triple helix is largely explainable by the unusual amino acid composition of the α chains. Specifically, each α chain of type I collagen has approximately 1000 amino acids, and glycine (Gly), the smallest amino acid, accounts for approximately one-third of the total number of amino acids, evenly distributed in the collagenous portion of the polypeptide. Consequently, the polypeptide chains of collagen can be described as repeating triplets represented as $(Gly\text{-}X\text{-}Y)_{333}$ (see Fig. 61-2). The X and Y positions of the repeating sequence can be occupied by a variety of amino acids, but the X position is often occupied by proline and the Y position by hydroxyproline. These two amino acids account for approximately 22 percent of the to-

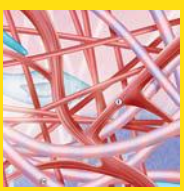
COLLAGEN, ELASTIC FIBERS, AND EXTRACELLULAR MATRIX AT A GLANCE



- The maintenance of tissue architecture and the physiologic properties of skin are attributable to the extracellular matrix of connective tissues.
- The connective tissue network comprises a large number of extracellular matrix components, including the collagens, elastic fibers, proteoglycan/glycosaminoglycan macromolecules, and several non-collagenous glycoproteins.
- The ability of resident cells, such as fibroblasts and smooth muscle cells, to synthesize and assemble the extracellular matrices is critical for morphogenesis, angiogenesis, and wound healing of the skin.
- In a number of pathologic situations, the dynamic balance between extracellular matrix synthesis and degradation is deranged, as exemplified by tumor invasion and metastasis, fibrotic skin diseases, and inflammatory processes.

▲ **FIGURE 61-2** Schematic representation of the structure of type I collagen. The collagen fibers (I), which on electron microscopy demonstrate a repeating periodicity (see Fig. 61-1), are composed of individual collagen molecules aligned in a quarter-stagger arrangement (II). Each type I collagen molecule is an approximately 300-nm-long rod-like structure (III) consisting of three individual polypeptides, known as *α chains*, which are twisted around each other in a right-handed triple helix (IV). Each chain is composed of amino acids in a repeating Gly-X-Y sequence (V); as indicated, the X position is frequently occupied by a prolyl residue, and the Y position is frequently occupied by a 4-hydroxyprolyl residue. The individual α chains have a left-handed helical secondary structure with a pitch of 0.95 nm. (From Uitto J et al: Collagen structure, function, and pathology, in *Progress in Diseases of the Skin*, vol 1, edited by Fleischmajer R. New York, Grune & Stratton, 1981, p 103, with permission.)

tal amino acid composition of type I collagen. The relatively high contents of these amino acids and the characteristic distribution of glycine in every third position are necessary for the triple-helical conformation of the collagen molecule, and hydroxyproline plays a critical role in stabilizing the triple helix at body temperature. The triple-helical conformation gives collagen many of its unique properties and is essential for normal fibrillogenesis. Mutations that affect the formation of the stable triple helix prevent collagen from forming fibers, which results in serious defects of connective tissue function and a spectrum of clinical phenotypes.[1–5]

Genetic Heterogeneity

Collagens comprise a family of closely related yet genetically distinct proteins. In the human genome there are as many as 42 different genes encoding α chains with variable amino acid sequences. These α chains correspond to at least 28 different types of collagen, which have been assigned Roman numerals I to XXVIII (Table 61-1). In addition to well-characterized collagens, short, triple-helical collagenous segments are present in other proteins, including acetylcholinesterase, the C1q component of the complement system, pulmonary surfactant proteins, macrophage scavenger receptors, emilins (elastin microfibril interface–located glycoproteins), and ectodysplasin A, a product of the gene mutated in X-linked anhidrotic ectodermal dysplasia.[6,7] These proteins are not included in the collagen family, however, because the collagenous domains are not a predominant part of the molecules, and the proteins do not function primarily as structural components of the extracellular matrix of connective tissue.

On the basis of the fiber architecture in tissues, the genetically distinct collagens can be divided into different classes (see Table 61-1). Collagen types I, II, III, V, and XI align into relatively large fibrils and are therefore designated *fibril-forming collagens*. Type IV is arranged in an interlacing network within the basement membranes, whereas type VI is a distinct microfibril-forming collagen and type VII collagen forms anchoring fibrils. *FACIT* (fibril-associated collagens with interrupted triple helices) collagens[8] include types IX, XII, XIV, XVI, XIX, XX, XXI, XXII, and XVI. Many of these collagens are associated with larger collagen fibers and may serve as molecular bridges important for the organization and stability of the extracellular matrices. Type XIII and XVII collagens are transmembrane proteins. Collagen types XX through XXVIII have been described more recently, and their supramolecular structures remain unknown. An overview of the major collagen types contributing to skin physiology and pathology is presented in the following paragraphs. Other collagen types are not discussed in detail because they do not appear to be present in the skin in significant quantities or they seem not to contribute to the physiologic properties of dermis.

TABLE 61-1
Genetic Heterogeneity of Collagen

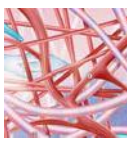
Collagen Type	Chain Composition[a]	Molecular Characteristics/ Supramolecular Assembly	Tissue Distribution/Cell Source[b]
I	$[\alpha1(I)]_2\alpha2(I)$	Fibrillar	Skin, bone, tendon
I-trimer	$[\alpha1(I)]_3$	Fibrillar	Tumors, skin
II	$[\alpha1(II)]_3$	Fibrillar	Cartilage
III	$[\alpha1(III)]_3$	Fibrillar	Fetal skin, blood vessels, gastrointestinal tract
IV	$[\alpha1(IV)]_2\alpha2(IV)$[c]	Basement membrane	Ubiquitous
V	$[\alpha1(V)]_2\alpha2(V)$; $[\alpha1(V)]_3$[c]	Fibrillar	Ubiquitous
VI	$\alpha1(VI)\alpha2(VI)\alpha3(VI)$	Microfibril	Ubiquitous
VII	$[\alpha1(VII)]_3$	Anchoring fibril	Papillary dermis of the skin and other epithelial tissues (gastrointestinal tract, trachea, esophagus)
VIII	$[\alpha1(VIII)]_3$	Network forming	Endothelial cells
IX	$\alpha1(IX)\alpha2(IX)\alpha3(IX)$	FACIT	Cartilage
X	$[\alpha1(X)]_3$	Network forming	Hypertrophic cartilage
XI	$\alpha1(XI)\alpha2(XI)\alpha3(XI)$	Fibrillar	Cartilage
XII	$[\alpha1(XII)]_3$	FACIT	Tendons, ligaments, perichondrium, periosteum, cornea
XIII	$[\alpha1(XIII)]_3$	Transmembrane	Ubiquitous including epidermis (17 splice combinations known)
XIV	$[\alpha1(XIV)]_3$	FACIT	Skin, tendons, cornea
XV	$[\alpha1(XV)]_3$	Basement membrane	Ubiquitous
XVI	$[\alpha1(XVI)]_3$	FACIT	Skin, internal organs, cartilage
XVII	$[\alpha1(XVII)]_3$	Transmembrane	Hemidesmosomes of basal keratinocytes in dermal-epidermal junction of the skin
XVIII	$[\alpha1(XVIII)]_3$	Basement membrane	Ubiquitous
XIX	$[\alpha1(XIX)]_3$	FACIT	Basement membrane
XX	Unknown	FACIT	Corneal epithelia, embryonic skin, sternal cartilage, tendon, lung
XXI	Unknown	FACIT	Smooth muscle cell in blood vessel walls, developing heart
XXII	Unknown	FACIT	Tissue junctions
XXIII	Unknown	Transmembrane	Metastatic tumor cells
XXIV	Unknown	Fibrillar	Developing bone and cornea
XXV	Unknown	Transmembrane	Neurons
XXVI	Unknown	FACIT	Testis, ovary
XXVII	Unknown	Fibrillar	Cartilage, eye, ear, lung
XXVIII	Unknown	Basement membrane	Peripheral nerves

FACIT = fibril-associated collagens with interrupted triple helices.
[a]The precise chain composition of some of the recently described collagens is not known.
[b]The predominant tissue distribution is indicated; lesser amounts may be present in other tissues.
[c]Additional α chains exist (see text).

Type I collagen, the most widely distributed and most extensively characterized form of collagen, is found predominantly in bone and tendon and accounts for approximately 80 percent of the total collagen of adult human dermis. The type I collagen molecule contains two identical α chains, designated *α(I)*, and a third chain, called *α2(I)*, that is clearly different in its amino acid composition. Thus, the chain composition of type I collagen is $[\alpha1(I)]_2\alpha2(I)$.

Type III collagen, another genetically distinct form of collagen, predominates in gastrointestinal and vascular connective tissues, but it also represents approximately 10 percent of the total collagen in the adult human dermis.[9] Type III collagen is composed of three identical α chains, α1(III), distinguished from the chains of type I collagen by a relatively high content of hydroxyproline and glycine and the presence of a cysteine residue. Collagen types I and III form the relatively broad extracellular fibers that are primarily responsible for the tensile strength of the human dermis. Mutations in the type I and III collagen genes can result in connective tissue abnormalities in the skin and joints, among other tissues, in different forms of Ehlers-Danlos syndrome and fragility of bones in osteogenesis imperfecta.[1,3,5]

Type IV collagen is abundantly present in basement membranes.[10] In the skin, type IV collagen is found in the



basement membrane at the dermal-epidermal junction, primarily within the lamina densa, where it forms a lattice rather than the fibers characteristic of dermal collagens. The type IV collagen present in human skin is predominantly a heterotrimer, $[\alpha1(IV)]_2\alpha2(IV)$, although, occasionally, the homopolymers $[\alpha1(IV)]_3$ and $[\alpha2(IV)]_3$ may be assembled. The type IV collagen molecule is characterized by the presence of noncollagenous interruptions within the triple-helical domain, which confer flexibility on the molecule. More recently, four additional α chains—α3(IV), α4(IV), α5(IV), and α6(IV)—have been identified.[11] The type IV collagen molecules containing these subunit polypeptides appear to be expressed primarily in glomerular basement membranes, and their importance for renal physiology is indicated by the fact that mutations in the gene encoding the α5(IV) polypeptide result in Alport syndrome,[12] an X-linked renal disease. Furthermore, autoantibodies recognizing the α3(IV) chains underlie Goodpasture syndrome.[13] Finally, the α5 chain of type IV collagen has been shown to be a target of circulating immunoglobulin G autoantibodies in a novel autoimmune disease characterized by sub-epidermal blisters and renal insufficiency.[14]

Type V collagen consists of a subfamily of similar interrelated collagens that contain four different types of α chains. The predominant form in the skin is $[\alpha1(V)]_2\alpha2(V)$. Type V collagen is present in most connective tissues. In the skin type V collagen represents less than 5 percent of the total collagen. In dermis, type V collagen is associated with major collagen fibers consisting of type I and III collagens, and type V collagen has been postulated to regulate the fiber diameter during fibrillogenesis. The importance of type V collagen has been demonstrated by discovery of mutations in the type V collagen genes in patients with classical autosomal dominant forms (types I and II) of Ehlers-Danlos syndrome.[15,16] It is of interest that a clinically similar, classical type of Ehlers-Danlos syndrome can be based on absence of tenascin-X expression, which leads to an autosomal recessive form of the disease.[17,18] Tenascin-X is developmentally associated with collagen fibrillogenesis, and its absence could explain the presence of defective collagen fibers similar to those found in patients with mutations in the type V collagen genes.

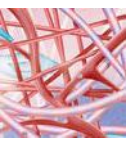
Type VI collagen is a relatively abundant component in a variety of tissues, including skin.[19] The type VI collagen molecules consist of three distinct α chains—α1(VI), α2(VI), and α3(VI)—which fold into a triple-helical domain of approximately 100 nm in length, with globular domains at both ends of the molecule.[20] Type VI collagen assembles into relatively thin microfibrils that form a network independent of the previously mentioned broad collagen fibers, which consist of type I, III, and V collagens. The microfibrillar network of type VI collagen may perform an anchoring function by stabilizing the assembly of the broad collagen fibers as well as basement membranes. Studies have now demonstrated that mutations in each of the three type VI collagen genes can lead to different forms of congenital muscular dystrophy, with multiple joint contractures, laxity of distal joints, and characteristic skin involvement.[21]

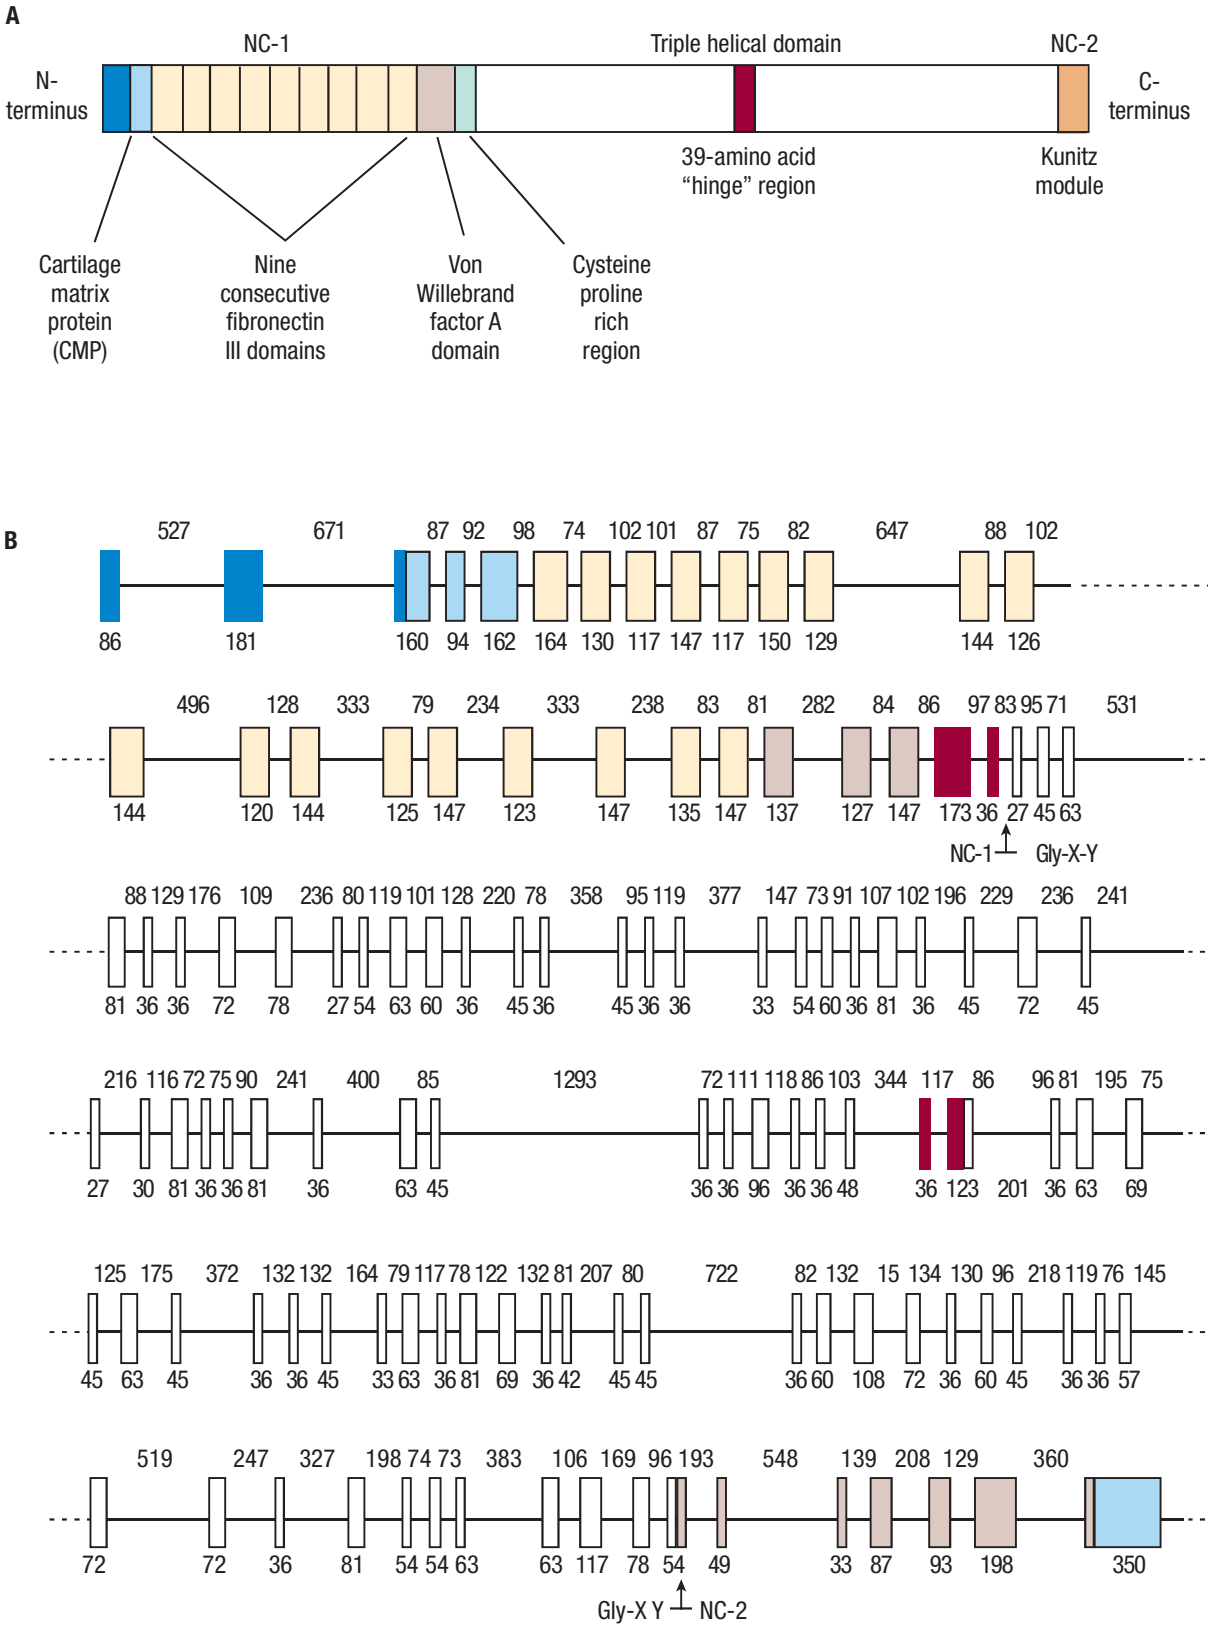
Type VII collagen—the major, if not the exclusive, component of the anchoring fibrils at the dermal-epidermal basement membrane zone—was originally designated as long-chain collagen because it has an unusually long triple-helical region of approximately 450 nm.[22] It has only one type of α chain, α1(VII), and the triple-helical collagenous domain is flanked by a large, nonhelical (noncollagenous) domain (NC-1) at the amino terminus and a shorter carboxyl-terminal nonhelical domain (NC-2). Type VII collagen molecules become organized into anchoring fibrils, which extend from the lower part of the lamina densa to the papillary dermis, through the formation of antiparallel dimers linked through their carboxyl-terminal ends. The large amino-terminal, non-collagenous domains of type VII collagen interact with type IV collagen and laminin-5 components of the dermal-epidermal basement membrane, and it has been suggested that most anchoring fibrils form U-shaped loops that entrap broad dermal collagen fibers consisting of type I and III collagens.[23] Thus, alterations in the expression, structure, or molecular interactions of type VII with other basement membrane components could result in skin fragility. Such a situation is exemplified by dystrophic epidermolysis bullosa (DEB), a group of mechanobullous diseases characterized by blistering of the skin after minor trauma[24,25] (see Chaps. 51, 60). In fact, distinct mutations in the type VII collagen gene, COL7A1, have been demonstrated in more than 400 families with different forms of DEB, and none of the families with DEB studied so far has revealed mutations in genes other than that encoding the α1(VII) polypeptide of type VII collagen.[25] Furthermore, type VII collagen serves as the autoantigen in the acquired form of epidermolysis bullosa, an autoimmune disorder with circulating anti–type VII collagen antibodies[26] (see Chap. 58).

Type XVII collagen was initially identified as the 180-kd bullous pemphigoid antigen *(BPAG2)*, which was recognized by circulating autoantibodies in the sera of patients with bullous pemphigoid or herpes gestationis. This antigen, which is synthesized by basal keratinocytes, was localized by immunoelectron microscopy to the hemidesmosomes at the dermal-epidermal basement membrane zone of human skin. Type XVII collagen is a transmembrane protein in type 2 topography; that is, the amino-terminal end is intracellular, whereas the carboxy-terminal ectodomain is in the extracellular space.[27] The ectodomain consists of 15 collagenous domains with the characteristic repeating Gly-X-Y sequences that form triple helices.[28] These collagenous domains are separated by non-collagenous segments of variable sizes, and consequently type XVII collagen is a protein characterized by alternating collagenous and non-collagenous segments.[27] The type XVII collagen gene was mapped to the long arm of human chromosome 10. This location is distinct from any previously mapped collagens and also distinguishes BPAG2 from BPAG1, the 230-kd bullous pemphigoid antigen, which has been mapped to the short arm of chromosome 6.[29] The importance of the type XVII collagen was also shown by mutations in the corresponding gene *(COL17A1)* that underlie a nonlethal variant of junctional epidermolysis bullosa, generalized atrophic benign epidermolysis bullosa (see Chap. 60).[27,30] These patients have protracted, lifelong blistering of the skin, atrophic scarring, alopecia, and nail dystrophy.

Collagen Gene Structure

The collagen genes, like most eukaryotic genes, are large, multiexon genes interrupted at several points by noncoding DNA sequences called *introns*.[31] Thus, the prototypic eukaryotic gene coding for a protein is much larger than would be predicted from the amino acid sequences of the final protein. An example of the complexity of collagen genes is the intron-exon organization of the type VII collagen gene *(COL7A1)* (Fig. 61-3), which consists of 118 exons, one of the largest numbers in any published gene.[32]





▲ **FIGURE 61-3** Structural organization of the type VII collagen polypeptide, the α1(VII) chain, as deduced from molecular cloning, and the intron-exon organization of the corresponding gene, *COL7A1*. **A.** The α1(VII) polypeptide consists of a triple-helical domain that contains imperfections or interruptions in the Gly-X-Y repeat sequence, including a 39–amino acid "hinge" region. The central collagenous domain is flanked by non-collagenous segments, the amino-terminal NC-1 domain, and the carboxyl-terminal NC-2 domain. The NC-1 domain consists of submodules with homology to known adhesive proteins, as indicated below the molecule. The NC-2 domain has a segment of homology with the Kunitz proteinase inhibitor molecule. **B.** The type VII collagen gene consists of a total of 118 exons (*vertical blocks*), which are separated from each other by intervening noncoding intronic sequences (*horizontal lines*). The sizes (in base pairs) of the introns (above the lines) and the exons (*below the blocks*) are indicated. Gly = glycine. [Modified from Christiano AM et al: Structural organization of the human type VII collagen gene (COL7A1), composed of more exons than any previously characterized gene. *Genomics* **21**:169, 1994, with permission.]

During the early stages of gene expression, the entire gene is transcribed into a high-molecular-weight precursor messenger RNA (mRNA), which is a complementary copy of the coding strand of the double-helical DNA. The precursor mRNA undergoes post-transcriptional modifications, such as capping and polyadenylation, and the introns are removed by splicing to yield a linear, uninterrupted coding sequence with 5′ and 3′ untranslated flanking regions. The mature mRNA is then transported into the cytoplasm and translated in cells, such as dermal fibroblasts, to the corresponding polypeptide.

With few exceptions, the collagen genes are widely scattered throughout the human genome.[1] For example, the genes coding for the two constituent polypeptide chains of type I collagen, α1(I) and α2(I), are located on separate chromosomes, 17 and 7, respectively. Knowledge of the precise chromosomal location of the genes coding for collagens in human skin has allowed identification of polymorphic markers within the genes and in the flanking DNA for use in genetic linkage studies. In addition, sophisticated mutation detection strategies, based on scanning of the genes, have led to identification of a large number of mutations in different collagen genes with characteristic phenotypic consequences.[1]

Translation of Collagen Polypeptides

Under physiologic conditions, fibril-forming collagen molecules spontaneously assemble into insoluble fibers. This observation presented a logistic problem, because it was difficult to visualize how a collagen molecule could be synthesized inside the cell and then secreted into the extracellular space without premature assembly of the molecules into insoluble fibers. The solution to this problem was found in the demonstration that collagen is initially synthesized as a larger precursor molecule, procollagen, that is soluble under physiologic conditions.

The precursor polypeptides of procollagen, so-called *pre-proα chains*, are synthesized on the ribosomes of the rough endoplasmic reticulum in fibroblasts and related cells (Fig. 61-4). This initial translation product, the pre-proα chain, contains an amino-terminal signal (or leader) sequence, a characteristic feature of many secreted proteins. The signal sequence is rich in hydrophobic amino acids and probably serves as a signal for attachment of the ribosomes to the membranes of the rough endoplasmic reticulum and vectorial release of the nascent polypeptides into the cisternae of the rough endoplasmic reticulum. During the transmembrane transport of the polypeptides, the signal sequence is enzymatically removed in a reaction catalyzed by signal peptidase (Table 61-2). The polypeptides released inside the lumen of the rough endoplasmic reticulum are termed *proα chains* and are larger than collagen α chains because they contain additional peptide sequences at both ends of the molecule. These non-collagenous extension peptides are different from the collagenous portion of the molecule in that they do not have glycine in every third position and often contain motifs homologous with sequences found as building blocks in other extracellular matrix proteins, such as the fibronectin III domain, von Willebrand factor A domain, and thrombospondin N-terminal domain sequences. It should be noted that, in spite of their homology, these domains do not have the functional characteristics of the original proteins.

Post-Translational Modifications of Polypeptide Chains

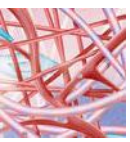
After the assembly of amino acids into pre-proα chains on the ribosomes, the polypeptides undergo several modifications before the completed collagen molecules are deposited into extracellular fibers (see Fig. 61-4). Most of these modification reactions are catalyzed by specific enzymes, and many of the modifications are characteristic of the biosynthesis of collagen (Tables 61-2 and 61-3). The post-translational modification reactions of collagen include (1) synthesis of hydroxyproline by hydroxylation of selected prolyl residues; (2) synthesis of hydroxylysine by hydroxylation of selected lysyl residues; (3) attachment of carbohydrates, galactose or glucosylgalactose, onto certain hydroxylysyl residues; (4) chain association, disulfide bonding, and triple-helix formation; (5) proteolytic conversion of procollagen to collagen; and (6) fiber formation and cross-linking. Current evidence indicates that modification reactions (1) to (4) are intracellular events, whereas proteolytic conversion, fiber formation, and cross-linking probably take place extracellularly (see Fig. 61-4).

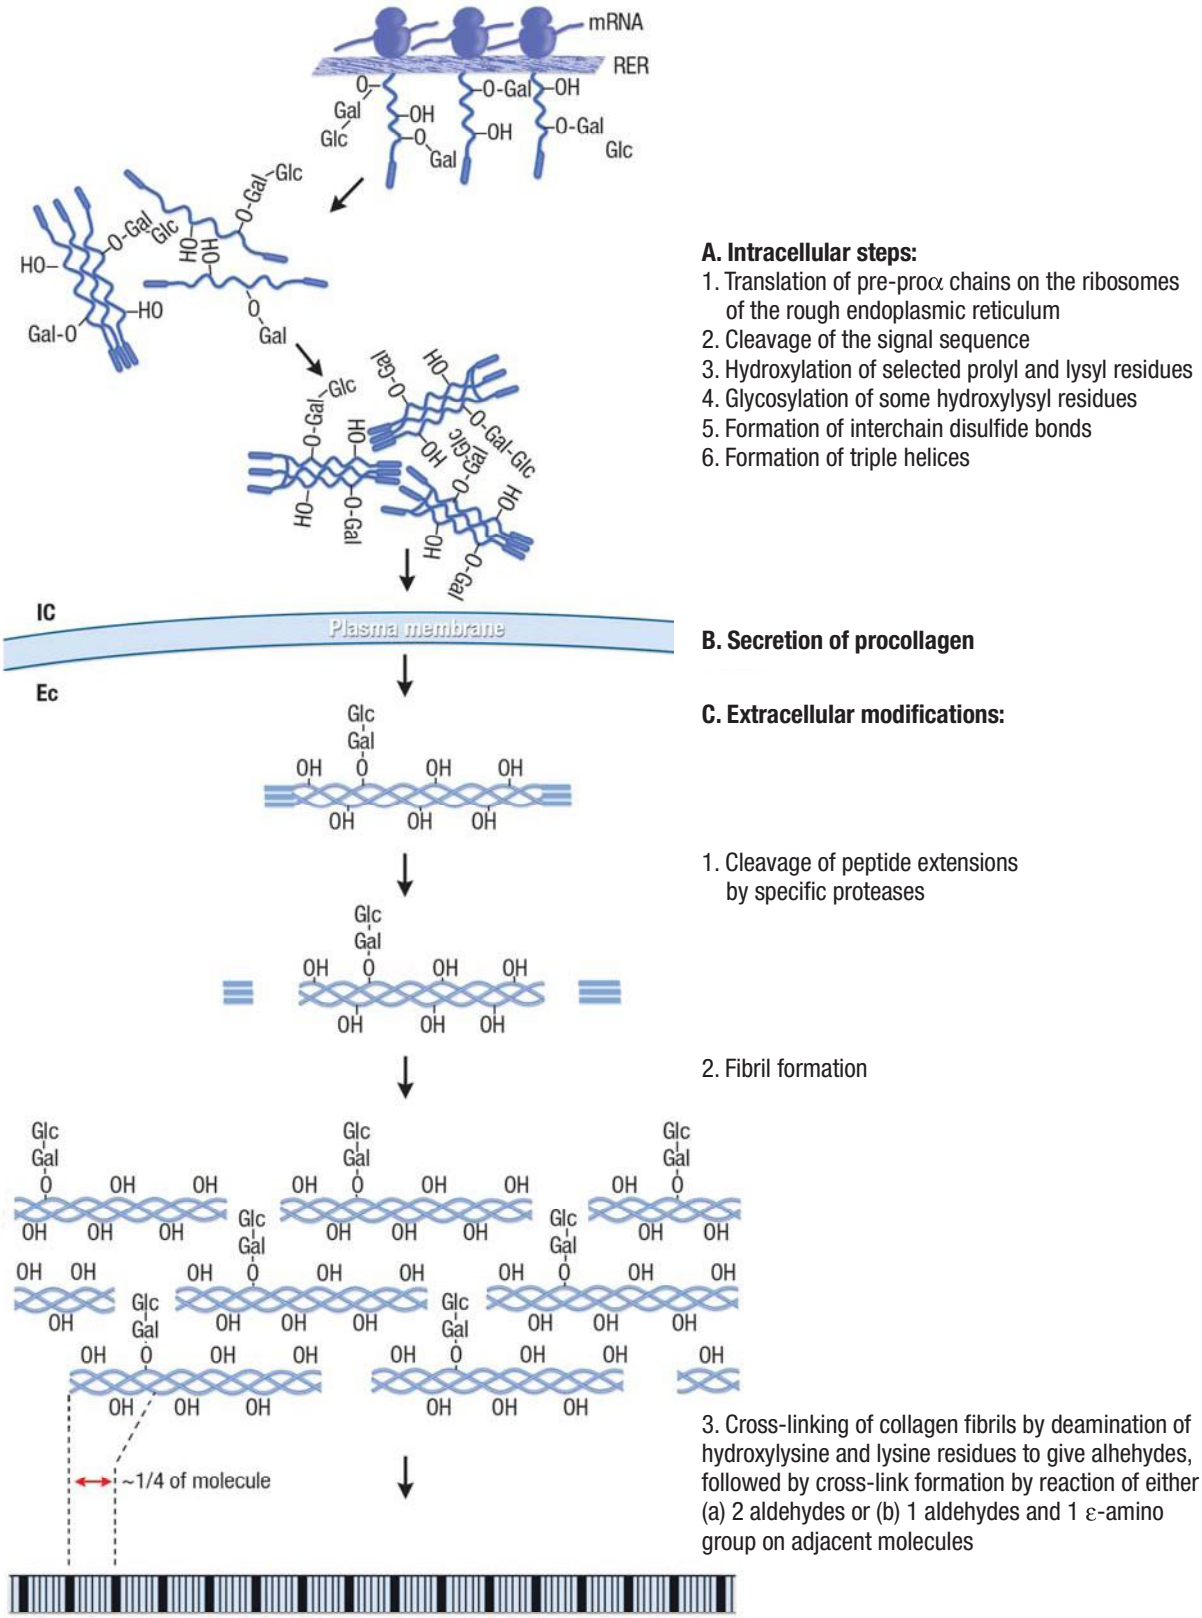
SYNTHESIS OF HYDROXYPROLINE A characteristic feature of collagen is the presence of relatively large amounts of hydroxyproline (Fig. 61-5). Small amounts of hydroxyproline are also found in elastin, as well as in some proteins in which the collagenous domains are a minor portion of the molecule, such as acetylcholinesterase, the C1q component of the complement system, the macrophage scavenger proteins, and ectodysplasin A (see refs. 1, 6, and 7). The hydroxyproline in collagen is found in two isomeric forms. *Trans*-4-hydroxy-L-proline accounts for more than 95 percent of the total hydroxyproline in type I and type III collagens. The minor form is *trans*-3-hydroxy-L-proline, which is found in greater amounts in type IV collagen. A critical amount of *trans*-4-hydroxy-L-proline is a prerequisite for the folding of α chains into the triple helix, the conformation required for the normal secretion of procollagen molecules out of the cells (Fig. 61-6). Thus, in the absence of hydroxyproline, collagen polypeptides would not form the critical triple-helical structure under physiologic conditions, and no functional collagen fibers would appear in the extracellular space.

The hydroxyprolines are synthesized by hydroxylation of certain prolyl residues that are already in the newly produced collagen polypeptides (see Fig. 61-5). The formation of *trans*-4- and *trans*-3-hydroxy-L-proline is catalyzed by two separate enzymes—prolyl-4-hydroxylase and prolyl-3-hydroxylase, which both require molecular oxygen, ferrous iron, α-ketoglutarate, and a reducing agent, such as ascorbate as co-substrates or co-factors for the reactions (see Fig. 61-5 and Table 61-2).

The hydroxylation of appropriate prolyl residues begins while the proα chains are growing on the ribosomes, and the hydroxylation is completed soon after the release of full-length polypeptide chains from the ribosomes. The enzyme prolyl-4-hydroxylase has been localized to the rough endoplasmic reticulum (see Fig. 61-6). Prolyl hydroxylases do not hydroxylate prolyl residues if the collagen substrate is in a triple-helical conformation. Because triple-helix formation takes place in the cisternae of the rough endoplasmic reticulum hydroxyproline formation must be completed before the procollagen molecules leave this cellular compartment.

Prolyl hydroxylase requires a reducing agent, such as ascorbate, for its activity. Therefore, ascorbic acid deficiency leads to a decreased formation of collagen fibers. This explains some of the clinical manifestations in scurvy, such as poor wound healing and decreased tensile strength of





A. Intracellular steps:

1. Translation of pre-proα chains on the ribosomes of the rough endoplasmic reticulum
2. Cleavage of the signal sequence
3. Hydroxylation of selected prolyl and lysyl residues
4. Glycosylation of some hydroxylysyl residues
5. Formation of interchain disulfide bonds
6. Formation of triple helices

B. Secretion of procollagen

C. Extracellular modifications:

1. Cleavage of peptide extensions by specific proteases
2. Fibril formation
3. Cross-linking of collagen fibrils by deamination of hydroxylysine and lysine residues to give alhehydes, followed by cross-link formation by reaction of either (a) 2 aldehydes or (b) 1 aldehydes and 1 ε-amino group on adjacent molecules

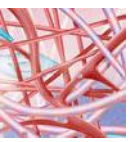
▲ **FIGURE 61-4** Biosynthesis of procollagen and the assembly of collagen molecules into the extracellular fibers. EC = extracellular; Glc-Gal = glucosylgalactose attached to a hydroxy-lysyl residue; IC = intracellular; mRNA = messenger RNA; –OH = hydroxyl group of hydroxy-proline or hydroxylysine; RER = rough endoplasmic reticulum.

the connective tissues.[33] An analogous situation may exist in tissues with relative anoxia, because molecular oxygen is a specific requirement for the formation of hydroxyl groups in hydroxyproline. Studies in animal models demonstrate that wound healing is relatively poor under hypobaric conditions, and in such situations the low oxygen levels may limit the synthesis of hydroxyproline.[34] This observation may also explain the decreased healing tendency of wounds and ulcers in peripheral

TABLE 61-2
Characteristics of Enzymes Participating in the Biosynthesis of Collagen

Enzyme[a]	Substrate	Product	Co-Factors and Co-Substrates
Signal peptidase	Nascent pre-proα chains	Proα chains	None known
Prolyl-4-hydroxylase	Prolyl residue in X-Pro-Gly sequence in proα chains[b]	4-Hydroxyproline	O_2, Fe^{2+}, α-ketoglutarate, ascorbic acid
Prolyl-3-hydroxylase	Prolyl residue in Pro-Hyp-Gly sequence in proα chains[b]	3-Hydroxyproline	O_2, Fe^{2+}, α-ketoglutarate, ascorbic acid
Lysyl hydroxylase	Lysyl residue in Lys-Gly, Lys-Ser, or Lys-Ala sequence in proα chains[b]	Hydroxylysine	O_2, Fe^{2+}, α-ketoglutarate, ascorbic acid
Collagen galactosyl transferase	Hydroxylysine in proα chains[b]	Gal-*O*-hydroxylysine	Mn^{2+}, UDP-galactose
Collagen glucosyl transferase	Galactosyl-*O*-hydroxylysine in proα chains[b]	Glc-Gal-*O*-hydroxylysine	Mn^{2+}, UDP-glucose
Protein disulfide isomerase[c]	Cysteine residues in the extensions of proα chains	S-S bonds stabilizing the correct protein conformation	Thiols
Procollagen N-proteinase (ADAMTS-2)	Procollagen or p_n-collagen	P_c-collagen or collagen[d]	Ca^{2+}
Procollagen C-proteinase	Procollagen p_c-collagen	P_n-collagen or collagen[d]	Ca^{2+}
Lysyl oxidases	Lysyl or hydroxylysyl residue in fibrillar collagen	Aldehyde derivatives of lysine or hydroxylysine	Cu^{2+}, O_2

ADAMTS = a disintegrin and metalloprotease with thrombospondin motifs; Ala = alanine; Gal = galactose; Glc = glucosyl; Gly = glycine; Hyp = hydroxyproline; Lys = lysine; p_c-collagen = collagen molecule with the C-terminal propeptide still attached whereas the N-propeptide has been removed; p_n-collagen = collagen molecule with the N-terminal propeptide still attached whereas the C-propeptide is cleaved off; Pro = proline; Ser = serine; UDP = uridine diphosphate.
[a]The action of these enzymes (with the exception of signal peptidase) is relatively specific to collagen; the complete sequences of procollagen synthesis and collagen degradation involve additional, less-specific enzymes, such as those of transcription and translation.
[b]These reactions are terminated when the proα chains fold into the triple-helical conformation.
[c]It has not been established whether the formation of interchain disulfides in procollagen involves enzymatic catalysis, as occurs in some other proteins, or whether their synthesis takes place spontaneously.
[d]If intact procollagen is used as a substrate, partially modified products are formed; however, if the partially cleaved proteins (p_n-collagen, p_c-collagen) serve as substrates, collagen is produced.



tissues that are anoxic due to relatively poor blood supply.

SYNTHESIS OF HYDROXYLYSINE Hydroxylysine is another amino acid characteristic of collagen (Fig. 61-7). During the intracellular synthesis of procollagen, hydroxylysine serves as an attachment site for the sugar residues and is critical to the formation of cross-links that stabilize the extracellular collagen matrix. Free hydroxylysine is not incorporated into nascent polypeptide chains, but certain lysyl residues in peptide linkages are converted to hydroxylysine. The hydroxylation reaction is catalyzed by an enzyme, lysyl hydroxylase, that, like the prolyl hydroxylases, requires oxygen, Fe^{2+}, α-ketoglutarate, and ascorbate as co-factors and co-substrates. The critical importance of lysyl hydroxylation of collagen can be seen from the effects of the deficiency of lysyl hydroxylase in patients with the scoliotic form (type VI) of Ehlers-Danlos syndrome, characterized by hyperextensible skin, loose-jointedness, severe kyphoscoliosis, and ocular fragility.

GLYCOSYLATION Collagen is a glycoprotein that contains galactosyl and glucosylgalactosyl residues attached to the molecule. These residues are attached to collagen polypeptides during intracellular biosynthesis in a sequential manner, so that a galactosyl residue is first added to the molecule and then a glucose moiety is attached to some of the galactosyl residues (see Figs. 61-4 and 61-5). The link between the carbohydrate unit and the polypeptide is an *O*-glycosidic bond through the hydroxyl group of hydroxylysine. Therefore, the synthesis of hydroxylysine is a prerequisite for the glycosylation of collagen. The two glycosylation reactions are catalyzed by separate, specific enzymes called *collagen galactosyl transferase* and *collagen glucosyl transferase* (see Table 61-2). These enzymes have been extensively purified from a variety of sources. Both of them use uridine diphosphate sugars as a source of the carbohydrate and require Mn^{2+} as a co-factor. Not only are sugars attached to the hydroxylysyl residues in the triple-helical portion of the molecule, but the nonhelical extension peptides contain complex carbohydrates, consisting mainly of mannose. The function of the sugar residues in collagen and also in the extension peptides is not known.

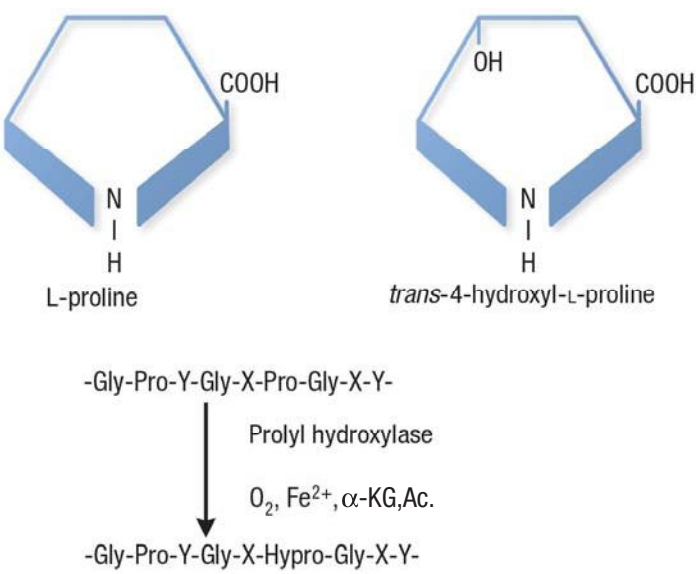
Chain Association, Disulfide Bonding, and Triple-Helix Formation

A critical step in the intracellular biosynthesis of procollagen is the association of three proα chains and subsequent folding of the collagen portion of the polypeptides into a triple helix (see Fig. 61-6). The non-collagenous peptide extensions on the individual proα chains assume globular conformations soon after their translation, and this conformation contains the specific information that directs the correct association of the three proα chains. Such a mechanism might explain the association of proα1 and proα2 chains in a proper 2:1 ratio during the synthesis of type I procollagen. It would also explain the rapid and efficient association of the proα chains and folding of the molecule into the triple helix. The association of the extensions at the carboxyl-terminal ends of the polypeptide chains appears to facilitate folding of the molecules into the triple helix, perhaps by providing a nucleation site from which the formation of the triple helix is propagated throughout the collagenous portion of the molecule.

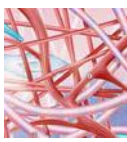
TABLE 61-3
Major Steps in the Biogenesis and Degradation of Collagen and Their Functional Significance

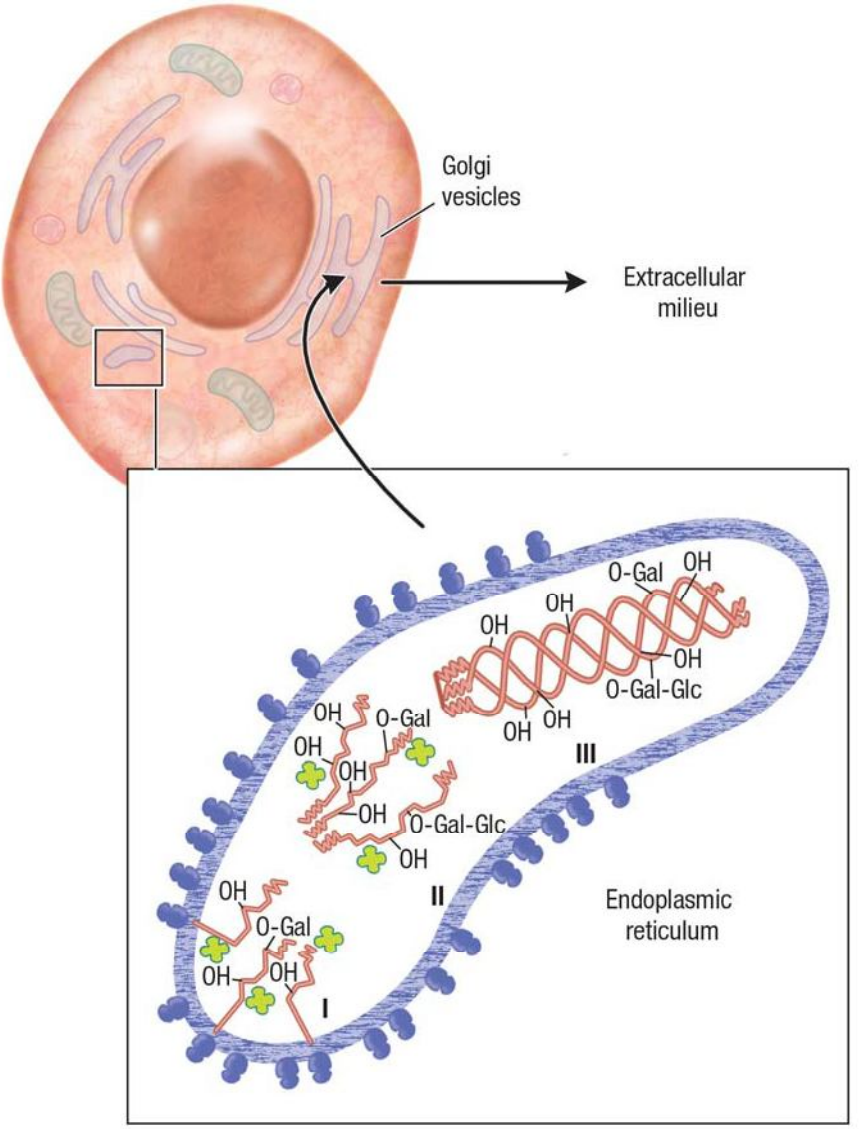
STEP[a]	FUNCTIONAL SIGNIFICANCE
I. Expression of genes coding for collagen polypeptides	
a. Gene selection	Determines the collagen isotype to be synthesized
b. Transcription	Formation of mRNA precursor
c. Processing of mRNA precursor	Formation of functional mRNA
d. Translation	Assembly of polypeptide chains
e. Control of the rate of transcription, mRNA processing, or translation	Determines the amount of polypeptide synthesized
II. Intracellular co-translational and post-translational modifications	
a. Removal of the signal sequence	May be necessary for secretion
b. Synthesis of 4-hydroxyproline	Stabilization of triple helix
c. Synthesis of 3-hydroxyproline	Unknown
d. Synthesis of hydroxylysine	Stabilization of covalent cross-links; attachment site for glycosylation
e. Synthesis of hydroxylysine-*O*-glycosides	May influence cross-link formation and determine the morphology and stability of the fibers
f. Glycosylation of the extension peptides	Unknown
g. Degradation of nonhelical chains	Removal of defective polypeptides and modulation of collagen production
h. Chain association and disulfide bonding	Facilitation of triple-helix formation
i. Triple-helix formation	Prerequisite for proper secretion
III. Secretion	Transport of procollagen through Golgi apparatus to the extracellular space
IV. Extracellular modifications	
a. Removal of the extension peptides from procollagen	Necessary for fiber formation
b. Deamination of certain lysine and hydroxylysine residues	Necessary for cross-link formation
c. Nonenzymatic glycosylation	May interfere with fiber formation
V. Fiber formation	
a. Alignment of the molecules	Formation of microfibrils
b. Formation of cross-links	Stabilization of the fiber structures
c. Supramolecular assembly	Architectural organization of collagen in tissues
d. Interactions with other extracellular macromolecules	Determine the physiologic properties of tissues
VI. Extracellular degradation	
a. Cleavage by specific collagenases	Rate-limiting step in degradation
b. Further degradation by peptidases and enzymes metabolizing free amino acids	Removal of degradation products

mRNA = messenger RNA.
[a]These are the major steps in the sequence in which they are likely to occur under physiologic conditions in vivo; however, some of the reactions can occur simultaneously or in reverse order.



◀ **FIGURE 61-5** Structures of proline (Pro) and hydroxyproline (Hypro), and schematic representation of the enzymatic hydroxylation of prolyl residues in the Y position of the repeating Gly-X-Y sequence of collagen polypeptides. Ac = ascorbic acid; Gly = glycine; α-KG = α-ketoglutarate. (From Uitto J, Prockop DJ: Inhibition of collagen accumulation by proline analogues: The mechanism of their action, in *Collagen Metabolism in the Liver*, edited by Popper H, Becker K. New York, Stratton Intercontinental, 1975, p 139, with permission.)





▲ **FIGURE 61-6** Representation of the synthesis and secretion of procollagen by a fibroblast. The enlarged area demonstrates events taking place in the rough endoplasmic reticulum of the cells during the synthesis of procollagen. In the first stage (I), the polypeptide chains of procollagen are synthesized on the membrane-bound ribosomes, and the nascent chains are fed into the cisternae of the rough endoplasmic reticulum. Hydroxylation of prolyl and lysyl residues and glycosylation of hydroxylysyl residues are initiated on the growing polypeptide chains, and these reactions are completed soon after release of full-size chains from ribosomes (II). Three proα chains are linked together by the formation of interchain disulfide bonds, and the collagenous portions of the polypeptides assume a triple-helical conformation (III). The procollagen molecules are then transferred from the rough endoplasmic reticulum to Golgi vesicles and are secreted from these vesicles into the extracellular milieu. –OH = hydroxyl groups of hydroxyproline and hydroxylysine; –Gal = galactosyl residue attached to hydroxylysine; –Gal-Glc = glucosylgalactosyl residue attached to hydroxylysine in O-glycosidic linkage; the cloverleaf-like structures signify the hydroxylating and glycosylating enzymes. (After Prockop DJ et al: Intracellular steps in the biosynthesis of collagen, in *Biochemistry of Collagen*, edited by Ramachandran GN, Reddi AH. New York, Plenum, 1976, p 163, with permission.)

Conversion of Procollagen to Collagen

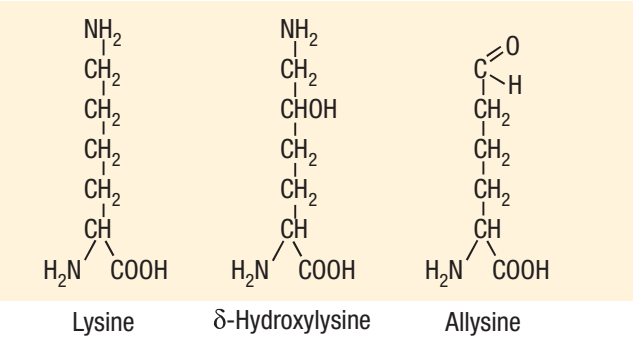
After secretion into the extracellular space, procollagen molecules are converted to collagen by limited proteolysis, which removes the extension peptides on the molecule.[35] The conversion of type I procollagen to collagen is catalyzed by two specific enzymes, procollagen N-proteinase and procollagen C-proteinase, that separately remove the amino-terminal and carboxyl-terminal extensions, respectively (see Table 61-2). Furthermore, the N-proteinase catalyzing the conversion of type III procollagen to collagen is a separate, specific enzyme.

The N-proteinase capable of cleaving type I procollagen belongs to the ADAMTS (a disintegrin and metalloprotease with thrombospondin motifs) family of extracellular proteases, and is specifically ADAMTS-2.[36,37] The activity of this enzyme is dependent on the native conformation of the amino-terminal propeptides in procollagen, because it does not catalyze the removal of the extension peptides from isolated proα chains. Furthermore, partially purified N-proteinase is inhibited by metal chelators, which suggests a requirement for divalent cations.

C-proteinase is required for removal of the carboxyl-terminal extension from types I, II, III, and V procollagens, which allows the fully processed molecules to form functional fibers.[35] Cloning of type I procollagen C-proteinase revealed that it is identical to bone morphogenic protein-1, a metalloprotease implicated in pattern formation during development of diverse organisms and also capable of inducing ectopic bone formation.[38,39] The activity of C-proteinase/bone morphogenic protein-1 is stimulated by procollagen C-proteinase enhancers, glycoproteins that bind to the C-terminal propeptide of type I procollagen.[40,41] Thus, the conversion of procollagen to collagen is a complex, carefully controlled process, and lack of removal of either the amino- or the carboxyl-terminal extensions results in impaired tensile strength of collagen fibers in the skin. Specifically, deficiency in the removal of the amino-terminal propeptide of type I collagen in vivo causes dermatosparaxis, a disease of fragile skin, originally recognized in various animal species, and more recently recognized in humans.[42,43] Specifically, the human counterpart is the dermatosparaxis type of Ehlers-Danlos syndrome (type VIIc), caused by deficiency in N-proteinase activity. It should be noted that a phenotypically similar disease, the arthrochalasia type of Ehlers-Danlos syndrome (types VIIa and VIIb), can be caused by mutations in the type I collagen genes (COL1A1 or COL1A2, respectively) at the cleavage site for the N-proteinase.[44]

Fiber Formation and Cross-Linking

After removal of the extension peptides in the extracellular space, the collagen molecules spontaneously align to form fibers. These fibers, however, do not attain the necessary tensile strength until



▲ **FIGURE 61-7** Structures of lysine, hydroxylysine, and allysine, the aldehyde derivative of lysine. (From Uitto J, Lichtenstein JR: Defects in the biochemistry of collagen in diseases of connective tissue. *J Invest Dermatol* **66**:59, 1976, with permission.)

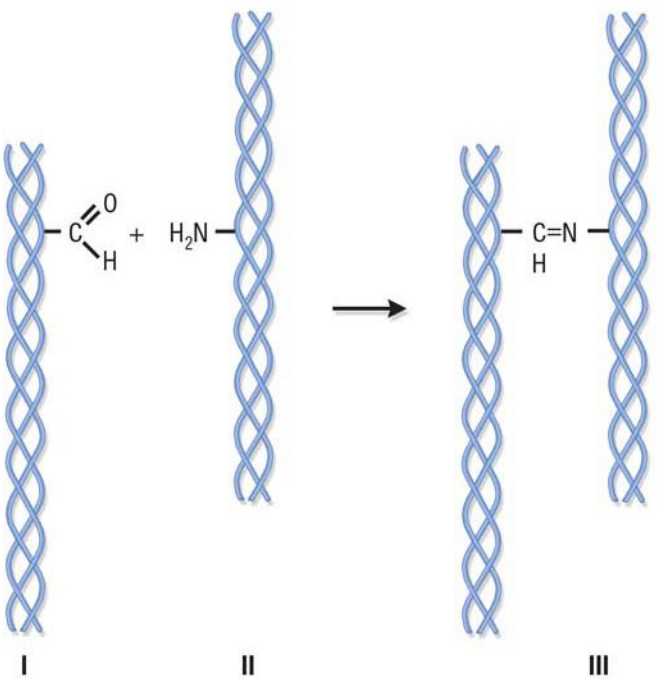
the molecules are linked together by specific covalent bonds known as *cross-links*.[45] The most common forms of cross-links in collagen are derived from lysine or hydroxylysine. The first step in the cross-linking of collagen is the enzymatic conversion of some of the lysyl and hydroxylysyl residues to corresponding aldehyde derivatives by removal of the epsilon-amino groups (see Figs. 61-4 and 61-6). The aldehydes then form cross-links by two kinds of reactions. One reaction involves condensation of an aldehyde with an epsilon-amino group still present in another unmodified lysine or hydroxylysine to form a Schiff base–type of covalent cross-link (Fig. 61-8). The second type of reaction is an aldol condensation between two aldehydes. In addition to these cross-links, collagen contains several more complex cross-links that also involve lysyl or hydroxylysyl residues. The lysine- and hydroxylysine-derived cross-links can be either intramolecular, occurring between two adjacent α chains in the same collagen molecule, or intermolecular, stabilizing the alignment of neighboring collagen molecules along microfibril structures.

The first step in collagen cross-linking, the oxidative deamination of certain lysyl and hydroxylysyl residues, is catalyzed by lysyl oxidase. This enzyme requires copper as a co-factor, and its activity is readily inhibited by nitriles, such as β-amino-propionitrile, which produce lathyrism in animals. Because the cross-links of collagen provide the tensile strength required in certain tissues, a defect in the formation of these covalent bonds can lead to a disturbance in connective tissue function. An example is occipital horn syndrome (previously known as *Ehlers-Danlos syndrome type IX*), which results from reduced lysyl oxidase activity (see Chap. 139). The primary defect resides in perturbed copper metabolism caused by mutations in a copper transport enzyme protein, an adenosine triphosphatase encoded by the gene MNK-1 that is also involved in Menkes syndrome.[46] As a result, serum copper levels are reduced, which leads to reduced lysyl oxidase activity.

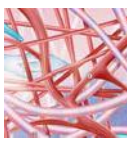
Control of Collagen Production

A major question in collagen biology concerns the mechanisms that control the deposition of collagen in tissues. Such control must exist in vivo, because the consequences of uncontrolled collagen accumulation are demonstrated by diseases such as progressive systemic sclerosis and various other fibrotic conditions.[47]

The accumulation of collagen in tissues can be controlled at several different levels of biosynthesis and degradation. Several observations suggest that an important control mechanism acts at the level of mRNA formation through regulation of the transcriptional activity of gene expression.[48] The transcriptional regulation of collagen gene expression involves both *cis*-acting elements and *trans*-acting factors. The *cis*-acting elements are nucleotide sequences in the promoter region of the gene that serve as binding sites for *trans*-acting cellular proteins, which can upregulate or downregulate the transcriptional promoter activity. Some of the *trans*-acting factors are nuclear receptors, such as the retinoic acid receptors (RAR and RXR)[49] that form a complex with the ligand (a retinoid) and then bind to the retinoic acid–responsive elements (RARE) in the target gene. Retinoids, such as all-*trans*-retinoic acid, modulate type I collagen gene expression both in vitro and in vivo. In particular, quiescent nonproliferating cells can be stimulated by retinoic acid to activate collagen gene expression. This may have rele-



▲ **FIGURE 61-8** Representation of the formation of intermolecular cross-links of collagen. The cross-linking is initiated by oxidative deamination of either a lysyl or hydroxylysyl residue to form a corresponding aldehyde derivative (I). The aldehyde then reacts with an epsilon-amino group on an unmodified lysyl or hydroxylysyl residue in an adjacent collagen molecule (II), and they form a Schiff base–type covalent cross-link. (From Uitto J, Lichtenstein JR: Defects in the biochemistry of collagen in diseases of connective tissue. *J Invest Dermatol* **66**:59, 1976, with permission.)



vance to the elevated collagen synthesis observed in photodamaged dermis after topical application of all-*trans*-retinoic acid (see Chap. 108).[50]

One of the most powerful modulators of connective tissue gene expression is transforming growth factor-β (TGF-β), a member of a family of growth factors that upregulate the expression of several extracellular matrix protein genes, including those encoding collagen types I, III, IV, V, VI, and VII.[51]

Degradation and Turnover

Extracellular matrix remodeling is a cooperative multi-step process involving localized degradation of the existing matrix components, followed by cytoskeletal rearrangement, cell translocation, and the deposition of new extracellular matrix components. Although each of these steps is controlled by a variety of molecular mechanisms, the initial step depends on the presence of proteinases capable of initiating the degradation of the matrix macromolecules. These enzymes comprise the matrix metalloproteinase (MMP) gene family,[52–54] which includes the collagenases, the gelatinases, the stromelysins, the matrilysins, metalloelastase, enamelysin, and the membrane-type MMPs (Fig. 61-9 and Table 61-4).

Interstitial collagenase (MMP-1) was the first enzyme of the MMP family to be discovered and was defined by its ability to break down triple-helical collagen that is resistant to most proteases. Human skin collagenase was initially isolated in active form from culture medium of skin explants[55] and subsequently as a proenzyme from monolayer fibroblast cultures.[56] Many other cell types, including keratinocytes, synovial cells, and monocytes-macrophages, express an identical enzyme. Interstitial collagenase, like the other MMPs, contains intrinsic zinc in the active site and requires calcium for its activity and thermostabilization.

Interstitial collagenase degrades collagen types I, II, III, VII, and X (but does not degrade collagen type IV and V). At physiologic pH and temperature the enzyme catalyzes a single cleavage three-quarter of the distance from the amino terminus in each of the three polypeptide chains comprising the triple-helical, native collagen monomer. Collagenase specifically cleaves the α1(I) chains at a Gly-Ile (glycine-isoleucine) bond (residues 775 and 776) and the α2(I) chain at a Gly-Leu (glycine-leucine) bond in the homologous region. Ten other Gly-Ile or Gly-Leu bonds within the triple-helical domain of the interstitial collagens are not cleaved, which suggests that the local conformation of the collagenase cleavage site is a major factor in determining substrate specificity. This region is more hydrophobic than other parts of the collagen molecule and lacks hydroxyproline residues that stabilize the triple helix. Indeed, human fibroblast collagenase catalyzes multiple cleavages in the denatured chains of all collagen types at Gly-Ile and Gly-Leu bonds. Thus it appears that the triple helix of native collagen can drastically alter the ability of human fibroblast collagenase to catalyze cleavages that would be permissible from primary sequence consideration alone. Moreover, even under optimal conditions of cleavage, collagen degradation by human fibroblast collagenase proceeds slowly for an enzymatic process, with a turnover number of approximately 25 molecules of fibrillar collagen degraded per molecule of collagenase per hour.

Human neutrophil interstitial collagenase (MMP-8) attacks collagens at the same site as does fibroblast collagenase to produce the characteristic three-quarter/one-quarter collagen fragments. The cloned enzyme is highly homologous to fibroblast collagenase but has a molecular mass of 75 kd due to a high degree of glycosylation. It is not immediately secreted but is stored in neutrophil granules and released on stimulation. Although both fibroblast and neutrophil collagenases have similar affinities for types I and III collagen, fibroblast collagenase degrades soluble type III collagen with a higher turnover rate, whereas neutrophil collagenase degrades soluble type I collagen more rapidly.[56] For both enzymes, the differences in specificity against monomeric collagens are largely abolished when the substrates are reconstituted into the insoluble fibrillar forms found in tissues.

Important mechanistic information on collagen degradation has recently emerged, and specifically, it has been shown[57] that activated collagenase (MMP-1) moves processively on collagen fibrils in which the mechanism of movement is a biased diffusion with the biased component of the motion depending on the proteolysis of collagen and not on ATP hydrolysis. Most importantly, the closely related matrix metalloproteinases, MMP-2 (gelatinase), MMP-9, and the extracellular portion of the membrane associated metalloproteinase, MT1-MMP can also diffuse on collagen fibrils. These studies also show that a collagenolytic MT1-MMP complex exists at the cell surface. The MT1-

TABLE 61-4
Matrix Metalloproteinases (MMPs)

Enzyme	MMP Number	Alternate Name	Proenzyme Molecular Weight	Known Matrix Substrates
Interstitial collagenase	MMP-1	Type I collagenase	52,000	Collagens I, II, III, VII, VIII, X, entactin, tenascin, aggrecan, denatured collagens, interleukin-1β, myelin basic protein, L-selectin
Neutrophil collagenase	MMP-8	—	75,000	Collagens I, II, III, V, VII, VIII, X, gelatin, aggrecan, fibronectin
Collagenase-3	MMP-13	—	52,000	Collagens I, II, IV, IX, X, XIV, aggrecan
Gelatinase A	MMP-2	72-kd type IV collagenase	72,000	Denatured collagens, collagens IV, V, VII, X, XI, XIV; collagen I, species dependent; elastin; fibronectin; laminin; aggrecan; myelin basic protein
Gelatinase B	MMP-9	92-kd type IV collagenase	92,000	Denatured collagens, collagens IV, V, VII, X, XIV, elastin, entacin, aggrecan, fibronectin, osteonectin, interleukin-1β, plasminogen, myelin basic protein
Stromeylsin-1	MMP-3	Proteoglycanase	57,000	Proteoglycan core protein, laminin, fibronectin, collagens I, IV, V, IX, X, XI, gelatin, elastin, tenascin, aggrecan, myelin basic protein, entactin, decorin, osteonectin
Stromelysin-2	MMP-10	Transin-2	55,000	Proteoglycan core protein, collagens III, IV, V, laminin, fibronectin, elastin, aggrecan
Stromelysin-3	MMP-11	—	61,000	α1-proteinase inhibitor
Matrilysin	MMP-7	PUMP, matrilysin-1	28,000	Collagen IV, denatured collagens, laminin, fibronectin, elastin, aggrecan, tenascin, myelin basic protein
Matrilysin-2	MMP-26	Endometase	28,000	Gelatin, α1-proteinase inhibitor
Membrane-type MMP-1	MMP-14	MTI-MMP	63,000	Progelatinase A, denatured collagen, fibronectin, laminin, vitronectin, entactin, proteoglycans
Membrane-type MMP-2	MMP-15	MT2-MMP	72,000	Progelatinase A
Membrane-type MMP-3	MMP-16	MT3-MMP	64,000	Progelatinase A
Membrane-type MMP-4	MMP-17	MT4-MMP	70,000	Unknown
Membrane-type MMP-5	MMP-24	MT5-MMP	73,000	Progelatinase A
Membrane-type MMP-6	MMP-25	MT6-MMP	63,000	Unknown
Metalloelastase	MMP-12	—	54,000	Elastin, collagen IV, vitronectin, plasminogen, laminin, entactin, fibrinogen, fibrin, fibronectin
Enamelysin	MMP-20	—	54,000	Amelogenin, aggrecan
MMP-19	MMP-19	RASI-1	57,000	Gelatin, aggrecan, fibronectin
MMP-21	MMP-21	—	Unknown	Unknown
MMP-22	MMP-22	—	Unknown	Unknown
MMP-23	MMP-23	—	44,000	Unknown
Epilysin	MMP-28	—	56,000	Unknown

PUMP = punctuated metalloproteinase.

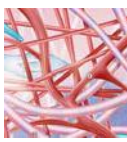
MMP complex anchored at the cell surface has profound implications concerning the generation of the forces required for cell locomotion, not only in the normal physiologic processes of tissue remodeling but also in pathologic processes, such as tumor invasion.

Collagenase-3 (MMP-13), first cloned from breast carcinoma, is homologous to rodent collagenase. The purified recombinant enzyme cleaves triple-helical collagens, giving the characteristic three-quarter/one-quarter fragments. Unlike interstitial and neutrophil collagenases, however, collagenase-3 acts 5 to 10 times more rapidly on soluble type II collagen, a cartilage-specific collagen, than on types I and III. Because of its preferential cleavage of type II collagen, and because it is made by both normal and osteoarthritic chondrocytes, collagenase-3 is thought to play an important role in osteoarthritis.

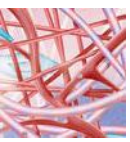
At physiologic temperature, the collagen cleavage products (i.e., the three-quarter/one-quarter fragments), which are initially triple helical, become soluble, are thermally unstable, and denature spontaneously, forming gelatin (denatured collagen). These denatured gelatin polypeptides are then susceptible to attack by other proteinases. Thus, the interstitial collagenases stand at a key point in connective tissue metabolism: They initiate the proteolytic events that result in the degradation of collagen and overall turnover of the extracellular matrices.

Collagen Diseases

The term *collagen disease* implies that a clinical condition involves an abnormality in the structure, synthesis, or degra-



dation of collagen. This term is frequently used to characterize a clinically heterogeneous group of inflammatory diseases, including lupus erythematosus, scleroderma, and dermatomyositis. In the classic nomenclature, the use of the term in these diseases was based on morphologic changes, known as *fibrinoid degeneration*, that have been interpreted to represent changes in collagen fibers. However, there is currently no conclusive evidence that fibrinoid degeneration of collagen fibers is indicative of a primary defect in collagen. On the basis of available biochemical evidence, scleroderma is the only clinical condition among the classic collagen diseases that involves any detectable abnormality in the structure or metabolism of collagen (see also Chaps. 62 and 158).



Collagen is an unusual protein in many respects, and its structure and metabolism involve a number of special features that are critical for deposition of normal collagen fibers. Based on our understanding of the biochemistry of normal collagen, it is now possible to identify discrete points at which defects could be introduced into collagen molecules or mature fibers. In a primary collagen disease, such a defect could be an inherited abnormality in the structure of the collagen or procollagen or in the enzymes participating in the biosynthesis and degradation of collagen.[1] In a secondary, acquired type of collagen disease, changes in collagen may be a consequence of initially unrelated metabolic changes. According to these definitions, several clinical disorders that are true collagen diseases are currently known. Indeed, there are many diseases in which a basic biochemical defect in collagen has been described, and several heritable connective tissue diseases with cutaneous involvement are now known to result from specific molecular defects in collagen genes (Table 61-5; see Chap. 139). Many of these diseases involve insertions, deletions, or single-base substitutions in the genes that alter the primary structure of the protein. In several acquired diseases, the regulation of collagen gene expression is disturbed, which leads to altered deposition of collagen in tissues. The diversity of collagen pathology is exemplified by Ehlers-Danlos syndrome and fibrotic skin diseases (see Chaps. 139 and 158). Ehlers-Danlos syndrome comprises a group of phenotypically similar conditions that frequently result from abnormalities in the structure of collagen or in enzymes modifying collagen molecules. In contrast, the fibrotic skin diseases exemplify conditions with altered regulation of collagen gene expression that leads to excessive accumulation of collagen in tissues.

TABLE 61-5
Heritable Connective Tissue Diseases with Cutaneous Involvement

Disease	Inheritance	Mutated Genes[a]	Affected Protein
Ehlers-Danlos syndrome	AD, AR	COL1A1, COL1A2, COL3A1, COL5A1, COL5A2	α chains of types I, III, and V collagens
		PLOD1, PLOD2	Procollagen-lysine, 2-oxoglutarate 5-dioxygenase (lysyl hydroxylase)
		ADAMTS-2	Procollagen N-peptidase
		TNX	Tenascin-X
		B4GALT-7	Xylosylprotein 4-β-galactosyl-transferase
Osteogenesis imperfecta	AD, AR	COL1A1, COL1A2	α1 and α2 chains of type I collagen
Cutis laxa	AD, AR, XR[b]	ELN	Elastin
		MNK-1 (ATP7A)	ATP-dependent copper transporter
		FBLN4	Fibulin-4
		FBLN5	Fibulin-5
Homocystinuria	AR	CBS	Cystathionine β-synthase
Menkes syndrome	XR	MNK-1 (ATP7A)	ATP-dependent copper transporter
Focal dermal hypoplasia	XD	ND	
Tuberous sclerosis (shagreen patches)	AD	TSK-1	Hamartin 1
Familial cutaneous collagenoma	AD	ND	
Epidermolysis bullosa	AD, AR	COL7A1, COL17A1	α1 chains of types VII and XVII collagen

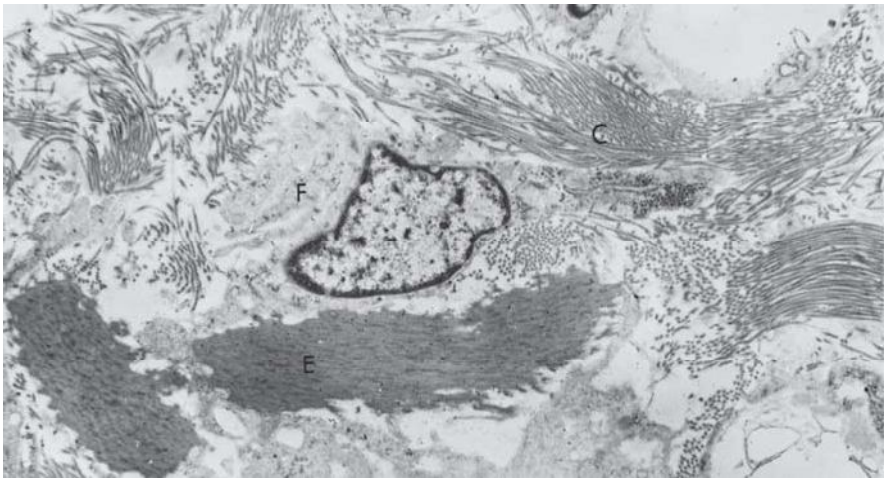
AD = autosomal dominant; AR = autosomal recessive; ATP = adenosine triphosphate; XD = X-linked dominant; XR = X-linked recessive; ND = not determined.
[a]For detailed discussion of these genes, see refs. 4 and 87.
[b]Most cases involve abnormalities in the elastic fibers, and in some cases, mutations in the elastin gene (ELN) have been disclosed. Occipital horn syndrome, a copper deficiency syndrome, allelic to the Menkes syndrome gene (MNK-1), was previously known as *X-linked cutis laxa* and also *Ehlers-Danlos syndrome type IX* (see Chap. 139).

ELASTIC FIBERS

Structure and Development of the Elastic Fibers

Elastic fibers of the connective tissue form a network responsible for the resilient properties of various organs.[58–60] The distribution of elastic fibers is variable in different tissues: their relative concentration is highest in the aorta and arterial blood vessels, but they are also abundant in the lungs. Elastic fibers are also present in the skin, although they are only a minor component (Fig. 61-10). Specifically, in sun-protected adult human skin, the elastin content is 1 percent to 2 percent of the total dry weight of dermis.[61] In the papillary dermis, elastic fibers are present either as bundles of microfibrils (oxytalan fibers) or with small amounts of cross-linked elastin (elaunin fibers). In the reticular dermis, the elastic fibers, which consist primarily of elastin, are oriented horizontally in a network with vertical extensions to the papillary dermis in the form of oxytalan fibers.

Examination of elastic connective tissues by transmission electron microscopy has demonstrated that mature elastic fibers consist of two distinct components (Fig. 61-11). The major component is a well-characterized connective tissue protein, elastin, and this amorphous, electron-lucent core, when visualized by transmission electron microscopy, is surrounded by distinct microfibrillar structures that have a regular diameter of 10 to 12 nm (see Fig. 61-11). The microfibrillar component is composed of a variety of proteins that have now been characterized.[58,60]



▲ **FIGURE 61-10** Transmission electron microscopy of human skin demonstrating a fibroblast (F) surrounded by elastic structures (E) and collagen fibers (C).

Elastin and the microfibrils exist in close association in various connective tissues; however, the relative proportions of these components vary during embryonic development. The first elements of elastic fibers that form during fetal development consist of bundles of microfibrils that can be visualized by electron microscopy early in the first trimester of gestation. It has been postulated that the microfibrils form a scaffold into which the elastin molecules align. During the second trimester, the elastic fibers remain relatively immature in structure and composition, but with increasing fetal age and maturation of the fibers, the amorphous elastin component becomes more prominent. Fully developed elastic fibers consist of a central amorphous core surrounded by an envelope of microfibrils, and electron microscopic estimations of the fully matured elastic fibers suggest that the elastin protein represents well over 90 percent of the total content of such fibers (see Fig. 61-11). It should be noted, however, that skin as well as other tissues contain microfibrils devoid of elastin.

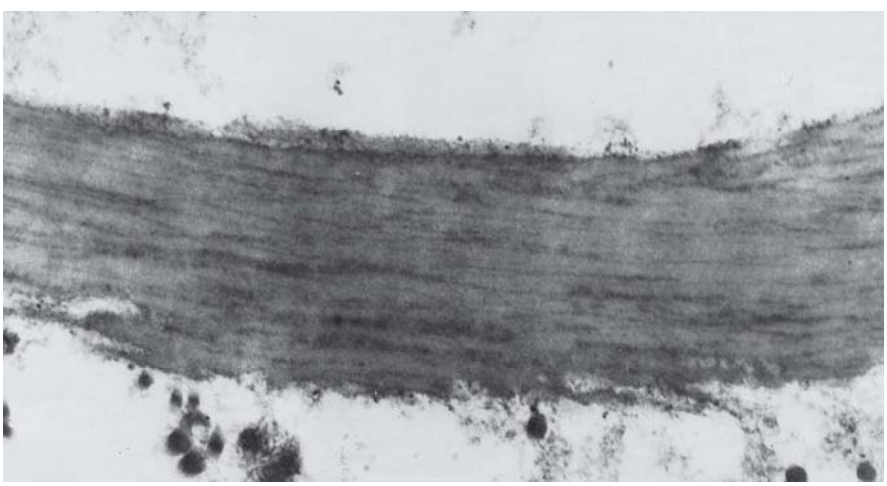
Biology of the Elastic Fibers

ELASTIN ***Protein Structure.*** The fibers composed of elastin, when visualized by scanning electron microscopy, appear as amorphous, branching structures forming continuous sheets in some connective tissues (Fig. 61-12). The isolation and characterization of the basic polypeptide unit of elastin were hindered for a long time by the extreme insolubility of elastin in mature animal tissues. It was discovered, however, that this insolubility is attributable to the presence of complex covalent cross-links, known as *desmosines* (see Fibrillogenesis and Cross-Linking), whose formation can be prevented by maintaining the animals on a copper-deficient diet or by feeding them lathyrogens, such as β-aminopropionitrile, which inhibit elastin and collagen cross-linking. Once the formation of the cross-links is prevented, a large fraction of newly synthesized elastin can be extracted from the tissues. By these methods, large quantities of soluble elastin were initially purified from porcine aorta, and short peptide fragments were sequenced.[62] The precise amino acid sequence of human elastin has now been deduced from cloned complementary DNAs (cDNAs).[63,64]

The basic molecular unit of elastin is a linear polypeptide, known as *tropoelastin*, that consists of approximately 800 amino acids with a molecular mass of approximately 70 kd. The amino acid composition of elastin is similar to that of collagen in that about one-third of the total number of amino acid residues consist of glycine. However, glycine is not evenly distributed in elastin, as it is in a typical collagen sequence. Instead, the glycine residues are grouped in valine- and proline-rich regions, which are interspersed with alanine-rich sequences. Elastin also contains some hydroxyproline, but the relative content of this amino acid is considerably lower than that in collagen, and the values for hydroxyproline are variable. Elastin does not contain hydroxylysine or carbohydrate moieties covalently linked to the polypeptide chain.

A characteristic feature of elastic fibers is the presence of cross-links that covalently bind elastin polypeptide chains into a fiber network. The two major cross-link compounds, desmosine and its isomer, isodesmosine, are structures that appear to be unique to elastin[65] (Fig. 61-13). The content of desmosines in various elastin preparations has been shown to be fairly constant, approximately 1.5 residues per 1000 amino acids. Consequently, assay of desmosine and isodesmosine can provide a quantitative measure of the elastin content in tissues.[66]

Gene Structure. Cloning of cDNAs corresponding to the human elastin mRNA, approximately 3.5 kilobases (kb) in size, has allowed elucidation of the entire primary sequence of tropoelastin[64] (Fig. 61-14). The deduced amino acid sequence depicts alternating segments of cross-link domains, characterized by the presence of lysyl residues separated by two or three alanine residues, and hydrophobic domains. The cross-link domains and the hydrophobic regions are en-



▲ **FIGURE 61-11** Transmission electron microscopy of the elastic fibers in normal human skin. Elastin, the electron-lucent core of the fiber, is surrounded by thin, electron-dense microfibrils. (Original magnification ×16,000.)

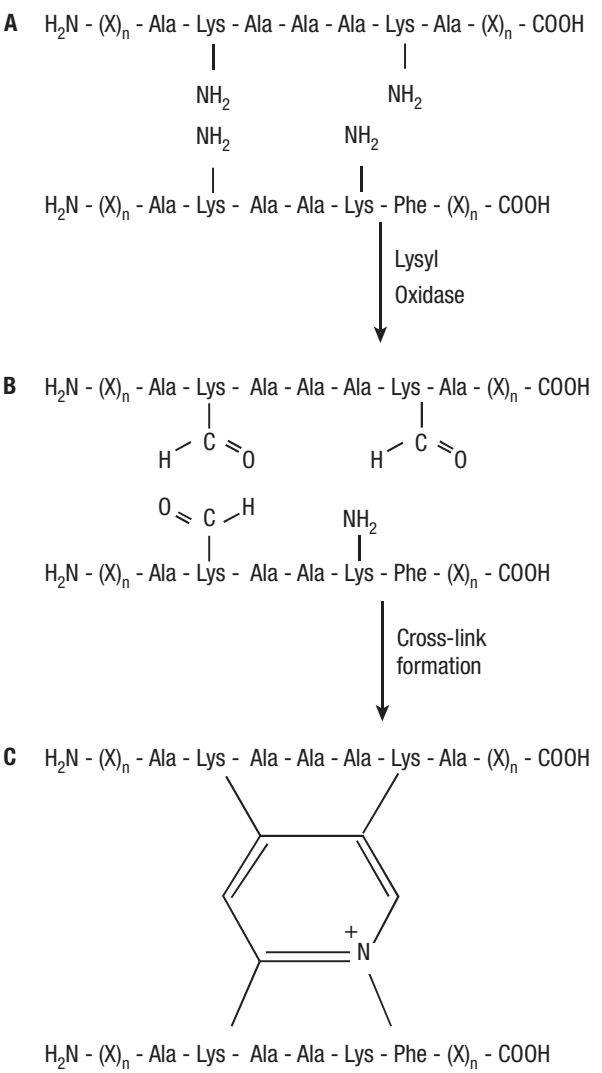
coded by separate exons.[67] The human elastin gene consists of 34 separate exons spanning a total of 45 kb of genomic DNA (see Fig. 61-14).

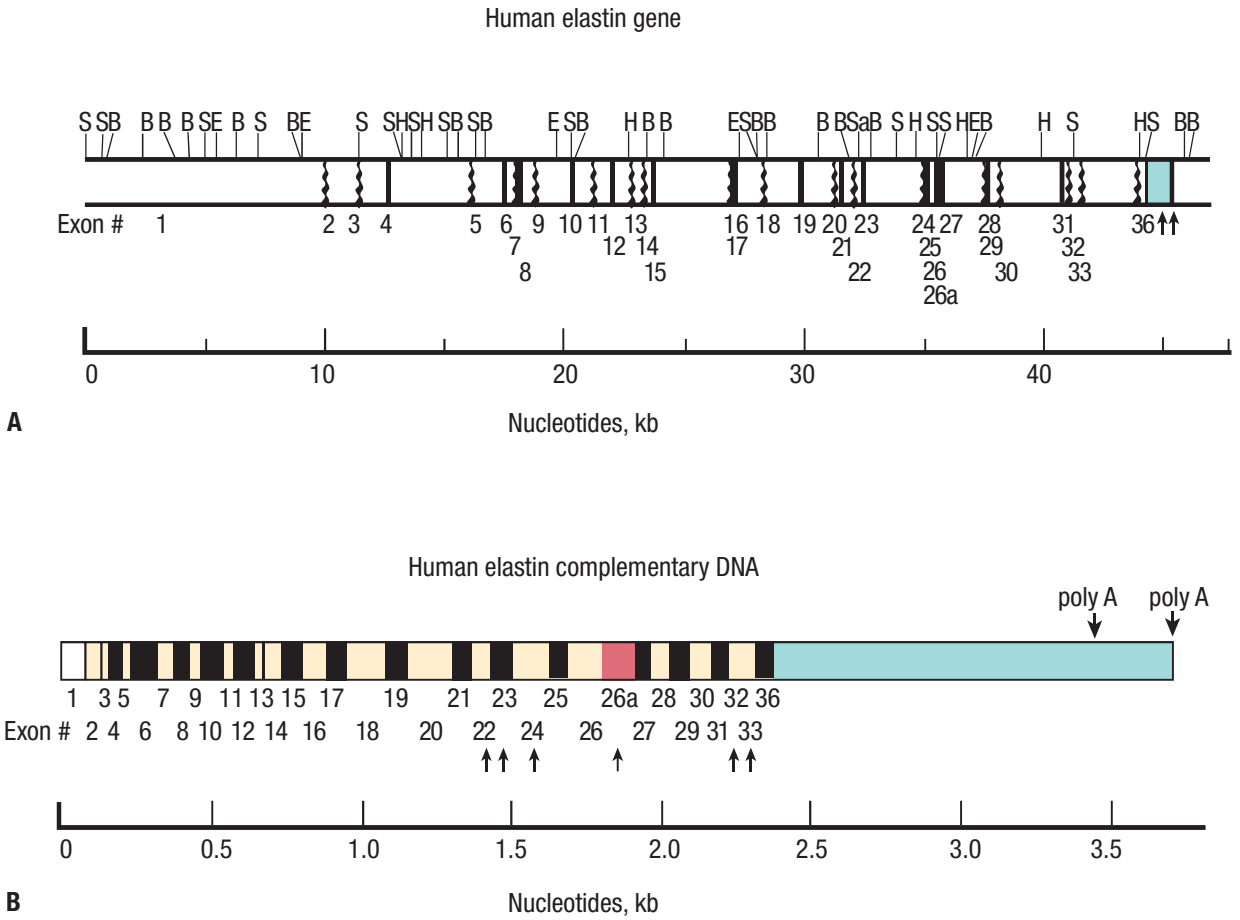
Constitutive and Alternative Splicing. The information stored in the DNA sequence of the elastin gene is transcribed in the nucleus of the cells to a large mRNA precursor, which undergoes several post-transcriptional modifications, including splicing and polyadenylation. The processed molecules are then transported to the cytoplasm, where the functional mRNAs serve as templates for the synthesis of elastin polypeptides during translation. Several lines of evidence suggest that the rate of elastin biosynthesis is largely regulated by the abundance of the functional mRNA, and consequently, assay of elastin mRNA levels allows measurements of the rate of elastin biosynthesis in tissues and cells.

An early observation during the isolation of human elastin cDNAs was that several overlapping clones were identical, with the exception of short sequences that were absent in some clones but present in others.[63,64,68] Comparison of these sequences in the cDNAs with the corresponding genomic DNA segments indicated that the differences were due to alternative splicing of certain exons during post-transcriptional processing of the elastin pre-mRNA. In fact, at least six exons in the human gene have been reported to be subject to alternative splicing, and several of the variant mRNAs are translated into protein. This mechanism can provide significant variation in the amino acid composition of individual elastin polypeptides and presumably in the function of the elastic fibers in different tissues. However, the developmental significance and tissue specificity of alternative splicing has not been elucidated in detail.



◀ **FIGURE 61-13** Formation of intermolecular cross-links, desmosine and isodesmosine, between two tropoelastin polypeptides. **A.** Amino acid sequences of a potential cross-link region within the tropoelastin polypeptides. Note the ε-amino group (NH_2) of the four contributing lysyl residues. **B.** Three of the lysyl residues undergo oxidative deamination catalyzed by lysyl oxidase to yield corresponding aldehyde derivatives, allysines. **C.** Three of the allysines and the fourth unmodified lysyl residue, still containing an epsilon-amino group, fuse into a stable desmosine cross-link. Ala = alanine; Lys = lysine; Phe = phenylalanine. (From Uitto et al: Elastic fibers of the connective tissue, in *Biochemistry and Physiology of Skin*, 2nd ed, edited by Goldsmith L. New York, Oxford University Press, 1991, with permission.)

Regulation of Elastin Gene Expression. The elastin promoter contains a remarkable constellation of potential binding sites for transcriptional regulatory factors indicative of complex transcriptional regulation. These include multiple *Sp1* and *AP2* binding sites, putative glucocorticoid-responsive elements, and TPA (phorbol ester tumor promoter, 12-O-tetradecanoylphorbol and cyclic adenosine monophosphate–responsive elements. The absence of a TATA box in the promoter region suggests that there may be multiple sites of transcriptional initiation, and various molecular tests confirm this fact.[67] Functional analyses



▲ **FIGURE 61-14** Representation of the human elastin gene (**A**) and the corresponding complementary DNA (cDNA) (**B**). **A.** The exons have been numbered starting from the 5′ end of the gene and correspond to those shown in the cDNA (see **B**). The presence of restriction endonuclease cleavage sites: *BamHI* (B), *EcoRI* (E), *HindIII* (H), *SacI* (S) is noted on top. **B.** The cDNA, approximately 3.5 kilobases (kb) in size, is divided into separate exons that are numbered from 1 to 36 and drawn to scale. Note that the human elastin gene contains only 34 exons; however, to maintain a consistent numbering system between the bovine and human elastin genes, the last exon is designated as number 36; thus, the human gene is missing the counterparts of bovine exons 34 and 35. The *arrows* indicate the exons that have been shown to be subject to alternative splicing. The arrows with poly A indicate the polyadenylation sites. (From Uitto et al: Elastic fibers of the connective tissue, in *Biochemistry and Physiology of Skin*, 2nd ed, edited by Goldsmith L. New York, Oxford University Press, 1991, with permission.)

of the human elastin promoter segment have been carried out by constructing a panel of promoter-reporter gene (such as chloramphenicol acetyl transferase) constructs.[69] These constructs have been used in transient transfections with a variety of cultured cells, including human skin fibroblasts. These studies indicate that the core promoter necessary for basal expression of the gene is contained within the region –128 to –1 (in reference to translation initiation site –1, +1), and the upstream sequences contain several upregulatory and downregulatory elements. Development of transgenic mice expressing the human elastin promoter has revealed that 5.2 kb of DNA flanking the human elastin gene contains the elements necessary for tissue-specific expression.[70] In addition to the 5′ upstream sequences, the first introns of both the bovine and human elastin genes contain regions of extremely strong sequence homology. Because it has been demonstrated that the first intron of three different collagen genes contains segments that act as enhancer elements of the promoter activity,[71] the strong conservation within intron 1 of the elastin gene suggests the possible presence of an enhancer in this gene as well.

Cytokine and Hormonal Regulation. The presence of multiple *cis*-acting elements in the elastin promoter region suggests that elastin gene expression is subject to modulation at the transcriptional level by *trans*-acting factors. For example, previous studies have indicated that tumor necrosis factor-α decreases elastin mRNA abundance primarily by suppressing promoter activity.[72] In other studies, TGF-β has been shown to upregulate the abundance of human elastin mRNA by up to approximately 30-fold,[73] but evidence from transient transfection assays suggests that this upregulation is, at least in part, post-transcriptional. In fact, assay of elastin mRNA half-life suggests that TGF-β stabilizes the elastin mRNA, which leads to elevated steady-state levels. These observations collectively suggest that mediators released from inflammatory cells can modulate elastin gene expression, and such modulation may play a role in diseases characterized by altered accumulation of elastic fibers in tissues.

Vitamin D_3 also modulates elastin gene expression. Specifically, incubation of fibroblasts with vitamin D_3 results in an 80 percent to 90 percent decrease in total accumulation of tropoelastin, accompanied by a parallel decrease in steady-state levels of the corresponding mRNA.[74] At the same time, insulin-like growth factor-1 enhances elastin gene expression at the transcriptional level.[75] Although there is preliminary evidence for modulation of elastin gene expression by selective growth factors and

hormone-like substances, the precise details are largely unknown.

Elastin Biosynthesis. Elastin biosynthesis involves several specific steps necessary for the assembly of elastic fibers. Several studies show that smooth muscle cells in culture synthesize relatively large quantities of elastin, which suggests that they may be the major source of elastin in tissues rich in elastic fibers, such as vascular connective tissue.[76] In addition to smooth muscle cells, human dermal fibroblasts in culture also express the elastin gene. The amount of elastin synthesized by cultured human skin fibroblasts is relatively small; nonetheless, fibroblasts may be the primary source of elastin in the dermis. Elastin gene expression has also been suggested to occur in cultured epidermal keratinocytes, although the level of expression in keratinocytes is very low in comparison to that in dermal fibroblasts, and the biologic significance of elastin gene expression in keratinocytes is unclear.[77]

After the completion of translation, newly synthesized polypeptides are translocated into the cisternae of the rough endoplasmic reticulum, in a manner similar to that occurring during the biosynthesis of collagen and other proteins destined for export from the cell. The polypeptides are then transferred from the rough endoplasmic reticulum into the extracellular space by transport mechanisms whose functioning, in the case of elastin, is not completely understood. It has been demonstrated, however, that incubation of cells synthesizing elastin with colchicine decreases the rate of elastin secretion and that the polypeptides accumulate intracellularly.[78,79] These observations suggest that the secretion of elastin polypeptides is a process that involves the microtubules of the cells and that the molecules may be transferred out of the cells packaged in Golgi vacuoles or related vesicles.

An interesting feature of elastin is the presence of 4-hydroxyproline. However, the relative hydroxyproline concentration in various elastin preparations is considerably lower than that in collagen. Amino acid analyses of elastin isolated from various sources indicate that the hydroxyproline content of the protein can vary from 7 to 25 residues per 1000 amino acids, and that hydroxyproline accounts for approximately 10 percent to 20 percent of the total imino acid (proline plus hydroxyproline) content of the molecule.[78,80] Previous studies clearly demonstrated that hydroxyproline plays an important functional role in the synthesis and secretion of collagen. In contrast, the presence of hydroxyproline is not required for the synthesis and secretion of elastin. This conclusion is based on studies in which cells synthesizing both elastin and procollagen are incubated with α,α-dipyridyl, an inhibitor of prolyl hydroxylase, which prevents the formation of hydroxyproline. Under such conditions, the cells continue to synthesize and secrete tropoelastin at the normal rate, whereas no intact triple-helical procollagen is recovered in the medium. The hydroxyproline found in elastin, therefore, appears to be a coincidental feature of the molecule in terms of synthesis and secretion of this protein.

Fibrillogenesis and Cross-Linking. The formation of desmosines occurs in the extracellular space, and the first step is the oxidative deamination of lysyl residues to corresponding aldehydes, known as *allysines*. This conversion is catalyzed by copper-requiring enzymes, lysyl oxidases.[81,82] The desmosines are formed by the fusion of three allysines and a fourth unmodified lysyl residue in two adjacent tropoelastin chains. Thus, the desmosines link the individual elastin polypeptides into an insoluble network (see Fig. 61-13).

Lysyl oxidases, a group of closely related enzymes, require copper and molecular oxygen as co-factors. It has been shown that in copper-deficient animals the activity of lysyl oxidases is reduced and the newly synthesized elastic fibers are not stabilized by the formation of desmosines.[83] Consequently, the individual tropoelastin polypeptides remain soluble and the elastin-rich tissues are fragile. Because lysyl oxidases are synthesized and secreted by human skin fibroblasts in culture,[84] these cells are presumably one source of the enzyme in vivo.

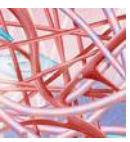
Degradation and Remodeling. Although the metabolic turnover of elastin is very slow compared with that of proteins in general, a portion of the body's elastin is continuously degraded and may partly be replaced by newly synthesized fibers.[85] In addition, degradation of elastin is markedly increased in a variety of pathologic conditions.[86] Thus, the tissues containing elastin must contain proteolytic enzymes that are capable of degrading elastic fibers.

Evidence for elastase, a specific elastolytic enzyme, was first obtained from study of the pancreas, and since then elastolytic enzymes have been detected in several other tissues, as well as in a variety of cell types, including polymorphonuclear leukocytes, monocytes/macrophages, and platelets.[87] However, elastases from different sources (pancreas versus polymorphonuclear leukocytes) have different cleavage specificities, as shown by peptide mapping of degradation products.[88]

The classic elastases are serine proteases that degrade insoluble elastic fibers at neutral or slightly alkaline pH. The activity of these enzymes is inhibited by serum factors, such as α_1-antitrypsin and α_2-macroglobulin. In addition to the classic elastases, which are serine proteases, others were shown to be metalloenzymes requiring calcium for their activity. One such enzyme is secreted by macrophages isolated from human alveolar macrophage exudates.[89]

Of particular dermatologic interest is the demonstration of elastase activity in the blister fluid from lesions of dermatitis herpetiformis and bullous pemphigoid (see Chaps. 59 and 54, respectively).[90,91] The elastase activity in the lesions of dermatitis herpetiformis is due to a serine protease and probably originates from polymorphonuclear leukocytes abundantly present in the lesions. The activity in the bullous pemphigoid lesions is caused by a metalloenzyme of unknown cellular origin. Regardless of the origin of the elastase activity, these enzymes could play a role in the development of the blisters by degrading the elastic fibers and other structures in the dermal-epidermal junction.

MICROFIBRILLAR PROTEINS Microfibrils consist of apparently tubular structures approximately 10 to 12 nm in diameter. Their staining properties and susceptibilities to enzymatic digestion differ from those of the amorphous elastin. At high resolution, the microfibrils appear in cross-section as an outer electron-dense shell surrounding an inner lucid core and in longitudinal section as a beaded chain, which suggests that they may be composed of more than one protein. Apparently similar microfibrils are present in many tissues, including those containing abundant elastin and those in which there is no visible or immunoreactive elastin, such as the ocular ciliary zonule and the periodontal ligament. In the dermis, the microfibrillary bundles that connect the deep dermal elastic plexus with the dermal-epidermal junction region consist of microfibrils indistinguishable from those associated with elastic fibers. In their



superficial distribution, no immunoreactive elastin is associated with them; but as they traverse the dermis, they are associated with an increasing amount of amorphous elastin.

Because of their insolubility and apparent complexity, chemical characterization of the microfibrils progressed slowly until recently. These structural proteins can now be divided into several groups based on their molecular characteristics. Table 61-6 lists these proteins and provides some distinguishing features, including their human chromosomal localizations. These groups include several gene families that share protein domain motifs.

Fibrillins. The largest of the microfibrillar proteins, and quantitatively and functionally perhaps the most important ones, are the fibrillins, 350-kd glycoproteins that form an integral part of the microfibril structure.[92,93] Electron microscopic images of human monomeric fibrillin synthesized by fibroblasts in culture show an extended flexible molecule approximately 148 nm long and 2.2 nm wide. Multiple fibrillin molecules align in a parallel head-to-tail fashion to form microfibrils. Molecular cloning studies have so far identified two distinct homologous human genes encoding fibrillins: fibrillin-1 (FBN1) and fibrillin-2 (FBN2).[93] Analysis of the fibrillin amino acid sequences, deduced from cloned cDNAs, showed that these proteins contain multiple repeats of a sequence motif previously observed in epidermal growth factor (EGF) precursor molecule, with each motif having six conserved cysteines.[92] Many of these repeats contain consensus sequences that have been associated with calcium binding. A second motif containing eight cysteines, originally found in latent TGF-β–binding proteins (LTBPs) has also been identified in the fibrillins (Fig. 61-15 provides a comparison of the structures of the fibrillins and LTBPs). Of interest is the report of a protein in jellyfish that has extensive homology to mammalian fibrillin; this thus identifies fibrillin as a very ancient protein that evolved well before elastin.[94]

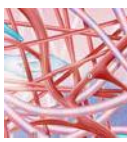
Latent Transforming Growth Factor-β–Binding Proteins. Several members of the LTBP family have been cloned and shown to contain repeating domains similar to those found in FBN1 and FBN2 (see Fig. 61-15). TGF-β is always secreted as a latent complex, and this complex is bound to a LTBP.[95] To date, four distinct LTBPs (LTBP1 to LTBP4) have been cloned and characterized, ranging in size from 125 to 310 kd. Although LTBPs may facilitate the secretion of TGF-β or binding of the inactive complex to the cell surface where activation takes place, they are also found as free proteins associated with components of the extracellular matrix. Development of an LTBP3 knockout mouse has revealed craniofacial malformations, perturbed ossification, and development of osteosclerosis and osteoarthritis in deficient animals.[96] These observations were interpreted to mean that LTBP3 is important for the control of TGF-β action and, specifically, that LTBPs may modulate TGF-β bioavailability.

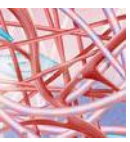
Immunohistologic studies have localized LTBP1 to microfibrils in elastic fibers, which strongly suggests that one or more of the LTBPs may be a component of these fibrils. Furthermore, levels of LTBP1 are altered in a number of

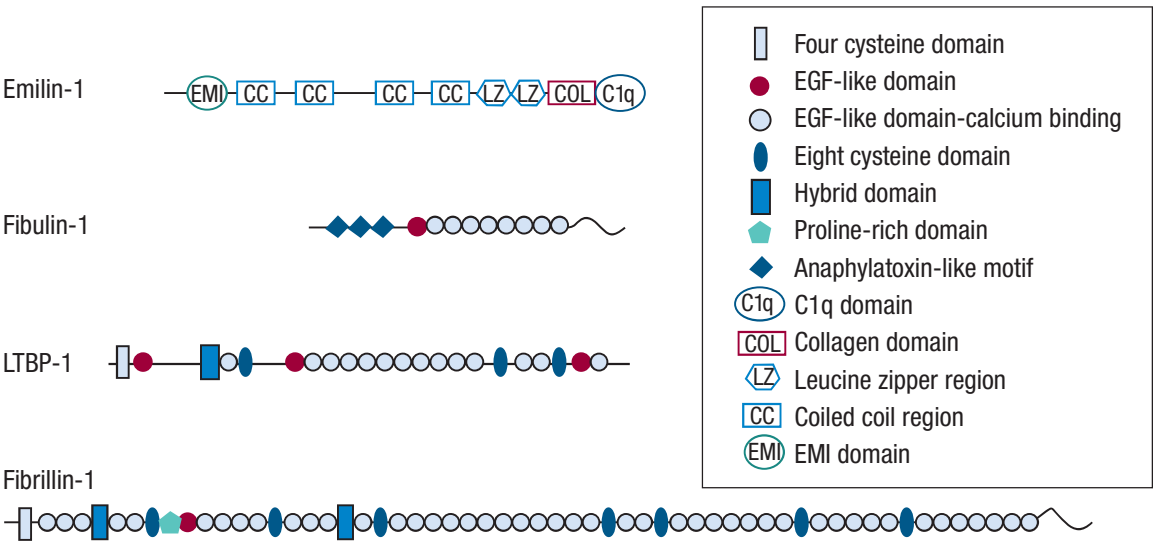
TABLE 61-6
Microfibrillar Component Proteins

Microfibrillar Protein	Characteristic Features	Human Chromosomal Locus
Fibrillins (FBNs)	350 kd Contain EGF- and TGF-β–binding protein motifs	
FBN1	Mutations in Marfan syndrome	15q15-q21
FBN2	Mutations in congenital contractural arachnodactyly	5q23-q31
FBN3		19p13.3-13.2
Latent TGF-β–binding proteins (LTBPs)	125 to 310 kd Contain EGF- and TGF-β–binding protein motifs Secreted as a complex with latent TGF-β but also found as a free protein	
LTBP1		2p22-24
LTBP2		14q22-q33
LTBP3		11q12
LTBP4		19q13.1-13.2
Fibulins (FBLNs)	60 to 240 kd Contain EGF and anaphylatoxin motifs	
FBLN1		22q13.3
FBLN2		3p24-p25
FBLN3		2p16
FBLN4	Mutations in cutis laxa	11q13
FBLN5	Mutations in cutis laxa	14q32.1
Microfibril-associated glycoproteins (MAGPs)		
MAGP1	31 kd; widely distributed in microfibrils	1p36.1-p35
MAGP2	25 kd	12p12.3-p13.1
Microfibril-associated proteins (MFAPs)		
MFAP1	Very acidic	15q15-q21
MFAP2		1p36.1-p35
MFAP3		5q32-q33.2
MFAP4	Frequently deleted in Smith-Magenis syndrome	17p11.2
βig-h3		5q31
Lysyl oxidases (LOXs)	Probably not structural components	
LOX		5q23-q31
LOXL1		15q24-q25
LOXL2		8p21.3-p21.2
LOXL3		2p13
LOXL4		10q24
Emilins		
Emilin1 (gp115)		2p23
Emilin2		18p11.3

EGF = epidermal growth factor; TGF-β = transforming growth factor-β.







▲ **FIGURE 61-15** Modular domain structures of selected elastin-associated microfibrillar proteins, including fibrillin (FBN), latent transforming growth factor-β–binding protein (LTBP), fibulin (FBLN), and emilin. The first member of each gene family is represented. The FBN, LTBP, and FBLN families are related because they share common protein motifs. EGF = epidermal growth factor; EMI = emilin-specific domain. New York, Wiley-Liss, 2002; Pan T-C et al: Structure and expression of fibulin-2, a novel extracellular matrix protein with multiple EGF-like repeats and consensus motifs for calcium binding. *J Cell Biol* **123**:1269, 1993; and Colombatti A et al: The EMILIN protein family. *Matrix Biol* **19**:289; 2000.)

pathologic conditions, including solar elastosis.[97]

Fibulins. The fibulins are a family of extracellular matrix glycoproteins that contain tandem EGF-like repeats similar to fibrillins and LTBPs.[98] Molecular cloning has identified as many as five distinct fibulin genes (see Table 61-6). The deduced amino acid sequences reveal that the molecules are modular and have the EGF-like repeats and a common carboxyl-terminal globular domain (see Fig. 61-15). Fibulin proteins are widely distributed in connective tissues, including the skin, and enriched in developing elastin-containing tissues. Fibulins 1, 2, 4, and 5 are located within the elastic fibers. FBLN5 binds both smooth muscle cells and elastin, thus facilitating the cell-matrix interactions. FBLN4- and FBLN5-deficient mice, developed by targeted ablation of the corresponding genes, demonstrate marked reduction in elastogenesis. FBLN4-deficient mice have a severe phenotype that leads to perinatal death, primarily due to pulmonary and cardiovascular abnormalities.[99] Particularly interesting is the clinical phenotype of FBLN-5 knockout mice, which show progressive laxity of skin in addition to vascular abnormalities and emphysematous lung changes.[100,101] The skin changes are reminiscent of those noted in patients with congenital cutis laxa. In fact, mutations in the FBLN4 and FBLN5 genes have been documented in some cases of cutis laxa.[102–104]

Other Microfibrillar Proteins. A number of other proteins unrelated to the fibrillins, LTBPs, and fibulins are constituents of the microfibrils. Such microfibrillar components include the lysyl oxidases,[81,82] interface proteins called *emilins*,[105] and several proteins belonging to the families of microfibril-associated proteins or microfibril-associated glycoproteins (see Table 61-6).[106–108] Among the latter, microfibril-associated protein 1 is remarkable in that it is extremely acidic, with glutamic acid comprising 23 percent and aspartic acid 6 percent of the residues. The extremely acidic nature of the protein suggests that it may have an important function in the assembly of the very basic tropoelastin molecules. Finally, lysyl oxidases are critical for the cross-linking and stabilization of the elastic fiber structures.

Pathology of the Elastic Fibers in Cutaneous Diseases

Several heritable and acquired connective tissue diseases have been shown to be associated with aberrations in the elastic fibers, including pseudoxanthoma elasticum, cutis laxa, and Buschke-Ollendorff syndrome (Table 61-7; see Chap. 139). In addition, clinically distinct entities with phenotypes closely resembling pseudoxanthoma elasticum (e.g., elastoderma) or cutis laxa (e.g., wrinkly skin syndrome) can be recognized.

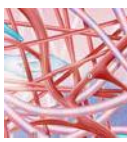
PROTEOGLYCANS AND GLYCOSAMINOGLYCANS

Proteoglycans and their glycosaminoglycan components constitute an important portion of the cellular membrane and extracellular matrix of the skin. Their ability to bind proteins and alter protein-protein interactions or enzymatic activities has identified them as important determinants of cellular responsiveness in development, homeostasis, and disease. Because proteoglycans are a structurally unique and highly diverse group of macromolecules, it is important to become familiar with their structure and organization in order to understand their function. The most distinguishing structural characteristic of proteoglycans is that they comprise both a core protein and covalently linked linear carbohydrate chains known as *glycosaminoglycans* (GAGs). GAGs are highly polyanionic and bear a high charge density. It has long been recognized that GAGs are a critical component of the skin, and more recently it has been appreciated that the content and composition of GAGs in the skin changes during development and in a variety of pathologic processes, and that both core protein and GAGs impart a unique set of functions that are critical to a large number of biologic processes.

TABLE 61-7
Clinical Features, Histopathology, Inheritance, Associated Biochemical Findings, and Predisposing Clinical Conditions in Cutaneous Diseases with Elastic Fiber Abnormalities[a]

Disease	Inheritance	Clinical Manifestations	Skin Histopathologic Findings	Biochemical Findings[b] Related to Elastic Fibers and Predisposing Clinical Conditions
Pseudoxanthoma elasticum	AR, sporadic[c]	Yellowish papules coalescing into plaques Inelastic skin Cardiovascular and ocular abnormalities	Accumulation of pleomorphic and calcified elastic fibers in the mid-dermis	Deposition of calcium apatite crystals, excessive accumulation of glycosaminoglycans on elastic fibers; D-penicillamine treatment; mutations in the *ABCC6* gene
Buschke-Ollendorff syndrome	AD	Dermatofibrosis lenticularis disseminata and osteopoikilosis	Accumulation of interlacing elastic fibers in the dermis	Increased desmosine content in the skin; mutations in *LEMD3*
Cutis laxa	AR, AD, or NH	Loose, sagging, inelastic skin Pulmonary emphysema Tortuosity of aorta Urinary and gastrointestinal tract diverticuli	Fragmentation and loss of elastic fibers	Decreased desmosine content and reduced elastin mRNA levels; increased elastase activity in some cases; D-penicillamine treatment, inflammatory and urticarial skin lesions (e.g., drug reaction); mutations in the *ELN, EBLN4,* or *FBLN5* gene in limited cases
DeBarsy syndrome	AR	Cutis laxa–like skin changes Mental retardation Dwarfism	Rudimentary, fragmented elastic fibers	Reduced elastin mRNA levels
Wrinkly skin syndrome	AR	Decreased elastic recoil of the skin Increased number of palmar and plantar creases	Decreased number and length of elastic fibers	—
Mid-dermal elastolysis	NH	Fine wrinkling of the skin, primarily in exposed areas	Fragmentation and loss of elastin in the mid-dermis	Inflammatory; sun exposure
Anetoderma	NH	Localized areas of atrophic, sac-like lesions	Loss and fragmentation of elastic fibers in the dermis	Reduced desmosine content in the lesions; often secondary to inflammatory lesions
Elastosis perforans serpiginosa	NH	Hyperkeratotic papules, commonly on the face and neck	Accumulation and trans-epidermal elimination of elastic fibers	D-penicillamine–induced abnormalities in elastin cross-linking
Elastoderma	Unknown	Loose and sagging skin with loss of recoil	Accumulation of pleomorphic elastotic material without calcification in the mid and lower dermis and the subcutaneous tissue	—
Isolated elastomas	NH	Dermal papules or nodules	Accumulation of thick elastic fibers in the dermis	—
Elastofibroma dorsi	NH	Deep subcutaneous tumor, usually on subscapular area	Accumulation of globular elastic structures encased in collagenous meshwork	Trauma on the lesional area
Actinic elastosis	NH	Thickening and furrowing of the skin	Accumulation of irregularly thickened elastic fibers in upper dermis	Long-term sun exposure
Marfan syndrome	AD	Skeletal, ocular, and cardiovascular abnormalities Hyperextensible skin Striae distensae	Fragmentation of the elastic structures in the aorta	Mutations in the *FBN1* gene
Congenital contractural arachnodactyly	AD	Camptodactyly and joint contractures		Mutations in the *FBN2* gene
Williams syndrome	AD	Supravalvular aortic stenosis Velvety skin Dysmorphic facies	Disruption of smooth muscle and matrix relationship affecting blood vessels	Allelic deletion of the *ELN* gene; contiguous gene deletion syndrome

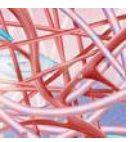
AD = autosomal dominant; AR = autosomal recessive; NH = not a heritable disease; mRNA = messenger RNA.
[a]Most of these conditions represent a group of diseases with clinical, genetic, and biochemical heterogeneity.
[b]The biochemical abnormalities have been demonstrated in only a limited number of patients in each group, and it is not known whether the biochemical changes are the same in each patient with any given disease.
[c]Rare cases with a distinct acquired form of pseudoxanthoma elasticum have been described.



Structure

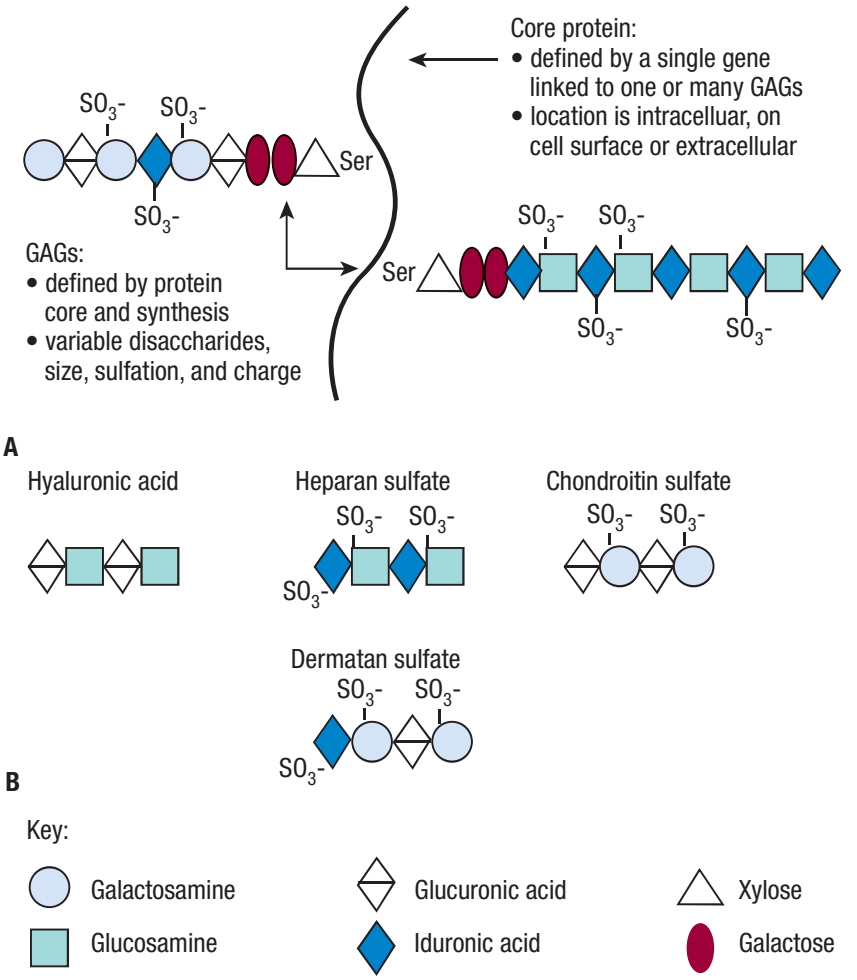
Historically, terms such as *ground substance* or *mucopolysaccharides* were used to describe proteoglycans because of their histologic appearance and their thick and mucinous nature when isolated. Because of these physical properties, proteoglycans were difficult to study and poorly understood. More recently, glycobiology has clearly defined proteoglycans as essential regulatory molecules that control many cellular functions. To attain this understanding, important advances have been made in the identification of specific proteoglycan core proteins and the assembly of their GAG side chains.

Proteoglycans are recognized as members of specific gene families based on amino acid sequence information derived from their core proteins and carbohydrate compositional analysis of their GAG side chains. The prototypical proteoglycan consists of a single core protein linked to one or more GAGs (Fig. 61-16A). Each core protein has the capacity to accept a variety of GAG chains. Consequently, the nomenclature for proteoglycans is complicated in that individual molecules must be defined based on the core protein and the associated GAGs.



Glycosaminoglycan Chain

The GAG chain is defined based on the assembly of essential sugar residues. These sugars are organized as disaccharide pairs that usually consist of an acidic sugar that is either an iduronic acid or glucuronic acid alternating with a hexosamine that is either glucosamine or galactosamine. When the chains are assembled as disaccharides, the choice of sugars and the linkage between them is used to assign a name to the GAG chain. Thus, several terms are used to define GAGs (see Fig. 61-16B), including *hyaluronic acid*, which contains a glucuronic acid alternating with *N*-acetylglucosamine–linked β1–3 and β1–4; *heparan sulfate*, containing iduronic or glucuronic acids alternating with *N*-acetylglucosamine–linked β1–4; *chondroitin sulfate*, containing glucuronic acid alternating with *N*-acetylgalactosamine–linked β1–3 and β1–4; and *keratan sulfate*, containing galactose alternating with *N*-acetylglucosamine–linked β1–4 and β1–3. A fifth general term used to describe GAGs, and of particular importance to cutaneous biology, is *dermatan sulfate*. This form of GAG (also known as *chondroitin sulfate B*) is similar to other chondroitin sulfates except that it contains a high proportion of iduronic acids in place of glucuronic acid and has more variable sulfation. Dermatan sulfate shares features of both chondroitin sulfate (*N*-acetylgalactosamine) and heparan sulfate (iduronate) (see Fig. 61-16B).



▲ **FIGURE 61-16** **A.** Prototype of proteoglycan structure. Core proteins may contain from 1 to 100 glycosaminoglycan (GAG) chains, depending on the core protein sequence. Two different GAG chains are shown: dermatan sulfate (*top left*) and heparan sulfate (*bottom right*). Sites of potential sulfation are indicated. *Ser* represents a serine amino acid residue in the core protein to which GAGs are attached. **B.** Disaccharide repeating units of GAGs shown as tetrasaccharides. Structures of heparan sulfate, dermatan sulfate, chondroitin sulfate A (chondroitin 4-sulfate)/C (chondroitin-6 sulfate), and hyaluronan are shown. Sulfation can vary in heparan sulfate and dermatan sulfate.

The linear chains of linked disaccharide units in a GAG are highly variable in size, ranging from as few as 10 disaccharides to several thousand. Thus, the mass of naturally occurring GAGs typically ranges between 5×10^3 d and 5×10^7 d for hyaluronic acid. Further variability is introduced into the GAG chain by epimerization reactions and sulfation reactions. The control of these reactions depends on the nature of the GAG, the core protein to which it may be attached, the cell type, and the cell environment. For example, the simplest GAG, hyaluronic acid, is never sulfated, whereas other GAGs can be sulfated to varying degree. The highly sulfated sugars tend to occur in specific regions of the GAG chain and are interspersed with areas of low sulfation. Such discrete domains of low or high sulfation are believed to determine the interactions between proteoglycans and GAGs and their many binding partners.

The size, disaccharide composition, and sulfation are of critical importance in understanding GAGs. These parameters influence function and are the mechanism by which instructions are defined within the molecule. Thus, the linear GAG should be considered as a molecule containing information, just as information is encoded in a protein. Synthesis of

GAGs (with the exception of hyaluronan) occurs in the Golgi apparatus, and the sequence information is determined by the activity and location of multiple specific enzymes along this pathway. Today, many of the synthetic enzymes that control heparan sulfate synthesis and those enzymes responsible for postsynthetic modifications have been identified and characterized.[109] The sulfated GAGs are all synthesized on core proteins. The tetrasaccharide xylose–galactose–galactose–glucuronic acid is first assembled on the core protein by beginning with a xylosyltransferase that forms a linkage between xylose and a serine residue in the core protein. Subsequent elongation reactions that occur in the Golgi apparatus define the nature of the GAG chain. It is appreciated that part of the information necessary to direct synthesis of the GAG is encoded within the core protein sequence itself. The final product, core protein with attached GAG, defines the proteoglycan (see Fig. 61-16A). Hyaluronan, the only GAG produced without attachment to a core protein, is synthesized by an enzyme complex at the plasma membrane and then extruded into the extracellular space.

Core Protein

Our understanding of proteoglycans has markedly advanced as a result of increased information about their core proteins and the subsequent use of molecular tools to study the expression and function of both the protein core and GAG components. Many specific proteoglycans can now be defined and studied based on their core protein sequences. For purposes of organization, it is useful to group proteoglycans according to their site of expression by the cell. Specific proteoglycan core proteins have been identified within the cell, attached to the cell surface, bound within the extracellular matrix, and released in soluble form (Table 61-8).

Serglycin is the best-known intracellular proteoglycan and is found within the secretory granules of hematopoietic cells, including mast cells, leukocytes, and eosinophils. This core protein is processed further to contain either heparan sulfate or chondroitin sulfate GAG. The heparan sulfate form is found in serosal mast cells and is a major source from which heparin is pharmacologically derived. The serglycin peptide core is composed primarily of tandem serine-glycine repeats and has an estimated mass of 16 to 18 kd before GAG addition and 60 to 750 kd after the addition of multiple heterogenous GAG chains.[110] Thus, serglycin is a unique proteoglycan because of its distinctive core protein sequence, and intracellular localization. In the skin, serglycin is found whenever mast cells or eosinophils enter the dermal stroma. On release, serglycin becomes a major source for the delivery of highly sulfated heparan sulfate GAG.

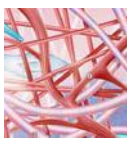
Several cell surface proteoglycans have been identified and are the subject of interest because of their ability to function at the interface between the plasma membrane and the extracellular environment. These cell proteoglycans can be found attached to the cell surface either by a phospholipid anchor (e.g., glypican family) or as membrane-spanning core proteins (e.g., syndecan family). The glypican family of core proteins shares the glycophosphatidyl inositol anchorage mechanism and a unique cysteine motif that is likely to impart a compact tertiary structure to the proteoglycans. Consequently, glypicans can be visualized as a compact protein presenting GAG chains in close proximity to the outer surface of the plasma membrane.

The surfaces of most cells contain another important family of proteoglycans known as the *syndecans*. Syndecans, like glypicans, are found in a wide variety of cells and tissues. The structure of these cell surface proteoglycans differs from that of the glypicans, however, in that syndecan core proteins consist of a short C-terminal cytoplasmic region, a transmembrane domain, and an extracellular region containing attachment sites for

TABLE 61-8
Core Proteins of Proteoglycans

Core Protein	Location	Usual GAG Component
Intracellular		
Serglycin	Mast cells, basophils	HS, CS
Cell surface		
Syndecan-1	Keratinocytes, other epithelia	HS, CS
Syndecan-2	Fibroblasts, endothelia, bone	HS
Syndecan-3	Neural cells, limbs	HS
Syndecan-4	Ubiquitous, lymphoid	HS, CS
NG-2	Neural, melanoma	CS
Glypican (GPC-1)	Brain, vascular endothelia	HS
Cerebroglycan (GPC-2)	Brain only	HS
OCI-5 (GPC-3)	Intestine and mesenchymal	HS
K-glypican (GPC-4)	Kidney, brain	HS
Glypican-5 (GPC-5)	Brain, kidney, bone	HS
Glypican-6 (GPC-6)	Intestine, kidney, lung	HS
Epican	Keratinocytes	HS, CS, KS
Betaglycan	Fibroblasts, epithelia	HS
Endocan	Endothelia	DS
Thrombomodulin	Endothelia	DS
Extracellular matrix		
Aggrecan	Cartilage	KS, CS
Versican	Fibroblasts	CS, DS
Brevican	Brain	CS
Neurocan	Brain	CS
Phosphocan	Brain	CS, KS
Decorin	Fibroblasts, others	DS
Biglycan	Bone	DS
Epiphycan	Cartilage	DS
OIF	Cartilage	
Fibromodulin	Fibroblasts	KS
Lumican	Cornea	KS
Agrin	Brain	HS
Perlecan	Basement membranes	HS
Bamacan	Basement membranes	CS

CS = chondroitin sulfate; DS = dermatan sulfate; GAG = glycosaminoglycan; HS = heparan sulfate; KS = keratan sulfate; NG-2 = NG2 proteoglycan; OIF = osteoinductive factor.



GAG chains. Unlike glypicans, syndecans span the plasma membrane and extend beyond the surface of the cell. In this way, syndecans are in a unique position to connect extracellular GAG to structures within the cytoplasmic space. The cytoplasmic domain imparts the ability of syndecans to participate in intracellular signal transduction via the protein kinase C pathway. Expression of syndecans is abundant in skin. Syndecan transcripts and proteins are expressed in distinct patterns during development[111] and in mature tissues.[112] Syndecan-1 is particularly abundant on keratinocytes and can vary the nature of attached GAG chains as keratinocytes differentiate.[113] During wound repair, syndecan-1 and syndecan-4 are highly induced in the dermis and granulation tissue.[114] Deletion of syndecan-4 from mice greatly decreases the rate of wound repair.[115] During malignant transformation, syndecan-1 expression decreases in the epidermis,[116] and expression can alter malignant behavior in select cell types.[117] Thus, syndecans have received particular attention as proteoglycans that modify cell function. Because syndecans and other proteoglycans can contain more than one GAG species, either simultaneously or under different cellular circumstances, GAG expression provides another mechanism of regulation in addition to protein expression.

The extracellular matrix contains multiple proteoglycans that have now been identified and studied. Aggrecan, a large proteoglycan found in cartilage, has been studied extensively. This core protein contains a region with over 100 serine-glycine dipeptides that serve as attachment sites for chondroitin sulfate GAG. The approximately 230-kd core protein can be modified to contain up to 130 GAG chains and have a final mass of approximately 2200 kd.[118] This densely packed multiple-GAG configuration has been described as a "bottle brush" to indicate the predicted structure. The aggrecan core protein also contains sites for keratan sulfate attachment and a domain for noncovalent binding to hyaluronic acid. As many as 100 aggrecan molecules can bind to a single hyaluronic acid molecule. Thus, the overall proteoglycan aggregate (from which the name *aggrecan* is derived) can have a mass near 200,000 kd.[118]

In the skin, fibroblasts produce large aggregating proteoglycans similar to aggrecan. The best known of these large proteoglycans is *versican*. The core protein of versican contains attachment sites for 12 to 15 GAG chains, which are primarily chondroitin sulfate or dermatan sulfate. Versican, like aggrecan, also binds hyaluronic acid, which enables it to form large aggregates. In skin, versican has been identified in the dermis (fibroblasts) and epidermis (keratinocytes) and demonstrates selective upregulation in response to TGF-β.[119] Thus, the size, distribution, and abundance of versican in the skin suggest that it is an important molecule in the regulation of the behavior of the skin.

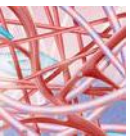
In addition to the genes encoding large aggregating extracellular matrix proteoglycans represented by aggrecan and versican, several genes encoding smaller proteoglycans have been identified in the extracellular matrix as well. One family of the proteoglycans is characterized by a leucine-rich repeat motif. The prototype of this family is decorin, an approximately 36-kd secreted proteoglycan. Decorin is found in abundance in skin and cartilage and is thought to be a ubiquitous component of connective tissue. The relatively small decorin core protein has a single dermatan sulfate chain covalently bound to a serine residue at amino acid position 4 and, like many other proteoglycans, also has *N*-linked oligosaccharides. Thus, after GAG addition, decorin can have a mass of 80 kd. Decorin received its name from observations that this molecule closely associates with collagen fibrils and can be seen to "decorate" the fibrils in vivo. This interaction is attributed to the ability of the decorin core protein to directly bind to collagen type I.[120] The single GAG chain of decorin also binds to tenascin-X, another extracellular matrix protein that colocalizes with collagen fibrils in connective tissues.[121] These binding interactions contribute to collagen fibril formation and influence function. Interestingly, similar phenotypes showing abnormal collagen morphology are seen in a patient deficient in tenascin-X and in the murine decorin knockout model.[122]

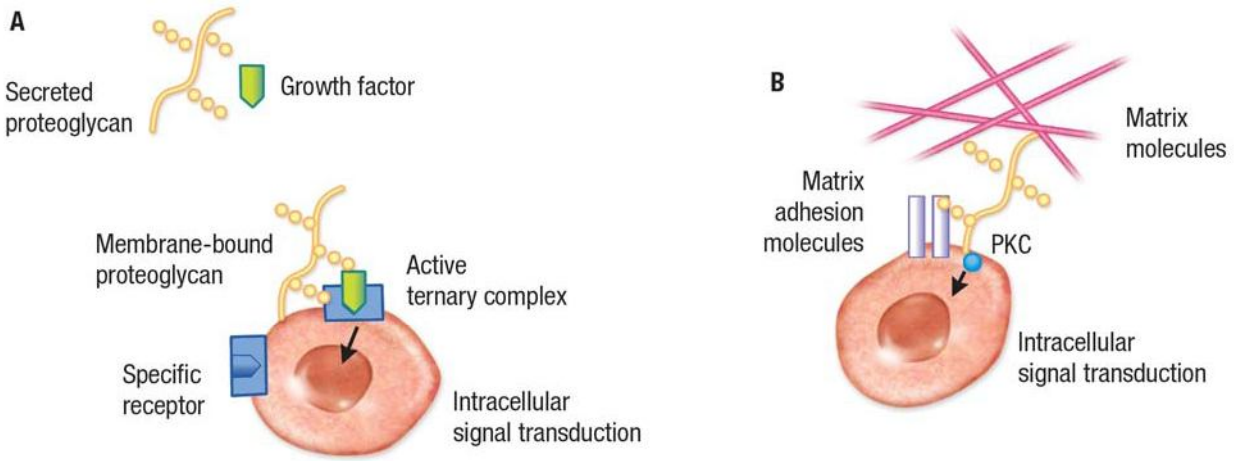
Function

To understand how proteoglycans function in the skin it is essential to appreciate the basics of their organization: (1) proteoglycans are part protein and part GAG; (2) GAGs are heterogeneous but encode specific information; (3) proteoglycan core proteins are expressed in different cellular compartments; and (4) proteoglycan expression and GAG composition vary according to cellular context. These characteristics are important, because the fundamental influence dictating proteoglycan function is the ability to bind to other molecules in its environment. Therefore, the sequences (both amino acid sequence and disaccharide sequence) of the core protein and GAG control proteoglycan function by influencing binding.

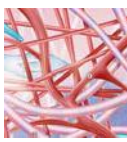
Similar GAGs can be found on multiple core proteins. This ability to interchange GAGs among cores adds complexity to the study of proteoglycan function. Therefore, in many cases, proteoglycan function is discussed purely in terms of the function of GAG chains. This implies that a number of genes encoding core proteins containing these GAGs may have a similar function. Fig. 61-17 illustrates some of the functions attributed to proteoglycans containing heparan sulfate and dermatan sulfate. The functions proposed for proteoglycans containing these GAGs derive from the ability of these molecules to bind to other components of the extracellular environment and mediate assembly of larger molecular complexes.

The list of molecules to which the major skin proteoglycans heparan sulfate and dermatan sulfate bind is quite extensive (Table 61-9). Therefore, several functions for proteoglycans have been proposed that include the particular biologic system in which the ligand is involved. Some of the most compelling experimental evidence for the functions of heparan and dermatan sulfate proteoglycans identifies the ability to bind several growth factors, cytokines, and components of the extracellular matrix.[123,124] Numerous laboratories have shown that heparan sulfate is required for the function of several growth factors, including several members of the fibroblast growth factor family,[125,126] hepatocyte growth factor/scatter factor,[127] and vascular endothelial growth factor.[128] In this model, the heparan sulfate proteoglycan can be found either at the cell surface or in a soluble form. The molecules then assemble to form a ternary complex at the cell surface between the growth factor, its specific high-affinity signaling receptor, and the proteoglycan (see Fig. 61-17).[129] Only after this ternary complex is formed does the cell receive the growth factor signal to begin to proliferate, differentiate, or migrate. The ability of dermatan sulfate to participate in these interactions has been demonstrated,[130,131] and the significance of this assembly to skin biology is apparent during wound repair. Heparan sulfate–dependent growth factors, such as members of the fibroblast growth factor family, are induced





▲ **FIGURE 61-17** Theoretical models for proteoglycan function. **A.** Proteoglycans as co-receptors for growth factors. Proteoglycan, growth factor, and specific receptor must all assemble at the cell surface before growth factor can activate the cell. Secreted extracellular proteoglycans may sequester and stabilize growth factors. **B.** Proteoglycans as extracellular matrix receptors. Proteoglycan can assemble with other matrix adhesion receptors (e.g., integrins) to aid in cell adherence. The proteoglycan syndecan-4 also interacts and signals through protein kinase C (PKC) to enable cell activation by matrix adhesion.



in a healing wound[132] and influence the wound repair process through the stimulation of keratinocyte proliferation, fibroblast growth, and angiogenesis. Heparan sulfate proteoglycans such as syndecan-1 and syndecan-4 are also induced at these sites[133] and enable activity of the growth factor. Because dermatan sulfate is the predominant GAG in wound fluid and because it can bind a variety of growth factors, cytokines, and extracellular matrix proteins, the further study of this GAG and the proteoglycans it comprises promises to be an exciting area for future investigation.

The influence of the proteoglycan core protein on cell behavior is thought to relate to the ability of the core protein to influence the amount and localization of GAG expression. In the example of wound repair, heparan and dermatan sulfate expression is influenced by the expression of the syndecan core proteins to which the GAGs are covalently attached. Other molecules, such as the syndecan inducer PR-39,[133] the syndecan inhibitor tumor necrosis factor-α,[134] and TGF-β, can have significant influence on the wound repair process by controlling GAG and proteoglycan expression.[135]

Study of the expression of proteoglycans has expanded the direct evidence for a function for these molecules. In addition to binding to growth factors, heparan sulfate proteoglycans play an important role in adhesion to the extracellular matrix. In the current model, cell surface proteoglycans, in conjunction with other matrix-binding molecules such as the integrins, help the cell adhere to the extracellular matrix (see Fig. 61-17). Syndecan-4 is selectively enriched in dermal fibroblasts at sites consistent with this function. Furthermore, the formation of these focal adhesions requires heparan sulfate and the subsequent activation of protein kinase C by a domain in the syndecan-4 core protein cytoplasmic tail.[136] In this setting, both the extracellular GAG and intracellular core protein of the proteoglycan have demonstrable function.

Other proteoglycans also interact with matrix molecules. Chondroitin sulfate and dermatan sulfate bind fibronectin and laminin.[137] As mentioned earlier, decorin, to which dermatan sulfate is typically attached, is known to associate primarily with type I collagen via its core protein.[120] In mice, selective disruption of the decorin gene leads to abnormal collagen morphology and increased skin fragility.[122] Thus, through targeted disruption of the gene in the mouse, the function of decorin as a stabilizer of collagen fibrils has been directly confirmed.

The function of the large extracellular matrix proteoglycans in skin is thought to relate primarily to the physical properties inherent in their large mass and charge density. Hyaluronan has been studied extensively from this perspective because of its extreme hydrophilicity and viscosity in dilute solution. As discussed earlier, hyaluronic acid is pure GAG and is synthesized extracellularly without a core protein. The genes for human hyaluronan synthase have been cloned and identified.[138,139] The expression of hyaluronan is developmentally regulated in skin and changes during wound repair. It has been proposed that the physicochemical properties of hyaluronan serve to expand the matrix and thus aid cell movements. Other physical properties attributed to GAG and large proteoglycan complexes, such as those formed with versican or basement membrane proteoglycans, include their ability to act as anionic filters and elastic cushions and their function in salt and water balance. In fetal skin, the high relative content of hyaluronan has been associated with the ability of fetal skin to heal without scar.

Multiple cutaneous disorders are associated with abnormal proteoglycan synthesis or deposition. A deficiency of decorin core protein has been described as the cause of a variant form of Ehlers-Danlos syndrome. Infectious disease is influenced by proteoglycan expression. For example, decorin-deficient mice are somewhat resistant to infection with *Borrelia burgdorferi*. Presumably this resistance is caused by a partial dependence of the organism on decorin for binding in the dermis.[140] During aging, the composition of GAG in the skin undergoes a marked change.[141,142] It has been proposed that the observed decrease in hyaluronic acid can explain diminished skin turgor in aged skin. Retinoids also effect this response.[143] In keloids, hyaluronic acid synthesis is elevated.[144] Thyroid hormone also has a marked effect on the synthesis of proteoglycans and GAGs. The manifestation of this response is seen in pretibial myxedema, in which the mucinous material deposited is predominantly hyaluronic acid and chondroitin sulfate. Other pathologic skin conditions, including pseudoxanthoma elasticum,

scleroderma, psoriasis, a variant form of Ehlers-Danlos syndrome, lichen myxedema, and ultraviolet B–irradiated skin, have also been reported to be characterized by abnormal amounts of proteoglycans. These associations do not imply that abnormal proteoglycan metabolism is responsible for these disorders, but they suggest that much of the pathophysiology of skin disease can be influenced by the function of cutaneous proteoglycans.

CHAPTER 62

Morphea

Vincent Falanga
Christina E. Killoran

MORPHEA

Localized scleroderma (LS), or morphea, differs from systemic sclerosis (scleroderma) by the presence of various cutaneous morphologic variants and the absence of clinically detectable systemic involvement. There may be overlaps in the pathogenesis of fibrosis in the localized and systemic forms.

Epidemiology

LS has been reported to have an incidence of 2.7 per 100,000.[1] There is a male–female ratio of 1:2 to 3, and the condition is more common in Caucasians and Asians than in African Americans.[2–4] All variants occur in adults and children and can occur at any age. Linear scleroderma is more common in children and can present in the first or second decade, whereas morphea and generalized morphea are more common in adults and usually present in midlife.[3–5] The relative frequency of the different morphologic variants is not clear, and reported studies have found different rates. In affected adults, 35 percent to 65 percent have plaque-type morphea, 8 percent to 9 percent generalized morphea, 6 percent to 46 percent linear scleroderma, 3.5 percent en coup de sabre, 3.5 percent morphea profunda, and less than 1 percent guttate, bullous morphea, and Parry-Romberg syndrome.[2,6] One study, which included 126 children, found that 48 percent of patients had plaque-type morphea, 17.5 percent linear, 14 percent mixed morphologic type, 8 percent Parry-Romberg, 3 percent generalized morphea, 3 percent en coup de sabre, 2 percent a keloidal form, and less than 1 percent had pansclerotic morphea of childhood, morphea profunda, or bullous morphea.[6]

The average duration of clinically active disease ranges from 3 to 6 years.[2,6] In chronic cases, slow clinical progression may persist for decades. Most patients will have a clinical remission of disease. Patients with plaque-type morphea are most likely to have the shortest disease duration. Rare patients, especially those with generalized morphea, morphea profunda, or linear scleroderma, will have a chronic course with several relapses, sometimes barely detectable clinically.[6]

Etiology and Pathogenesis

The etiology of LS is unknown. There are reports of morphea after infection with measles, varicella, and *Borrelia burgdorferi*. Other suggested triggers include trauma, bacille Calmette-Guérin vaccination, vitamin B injection, radiation therapy, penicillamine, and bromocriptine. However, no direct etiology has ever been proved. Suggested pathogenic events are similar to those hypothesized for systemic sclerosis. Endothelial cell damage, inflammation and release of cytokines that stimulate collagen production by fibroblasts, and an imbalance of extracellular matrix turnover in the skin seem likely. The reason for the limited distribution of LS is unclear, but the patterning suggests that mosaic genetic changes may contribute (see eFig. 62-0.1 in on-line edition).

Many studies have suggested a pathogenic role for transforming growth factor-β (TGF-β). TGF-β stimulates fibroblasts to produce increased amounts of glycosaminoglycans, fibronectin, and collagen; decreases extracellular matrix breakdown; and it diminishes fibroblast susceptibility to apoptosis. TGF-β has been found to be increased in lesions of LS as well as in the skin and fibrotic lungs of patients with systemic sclerosis.[7–11] Some work suggests that, at least in systemic sclerosis, TGF-β receptor expression in dermal fibroblasts is increased. There are also data supporting the possibility that alterations in the Smad protein pathway, which is important in TGF-β signal transduction, may play a role in collagen overproduction.[12–18] Fibroblast cultures derived from systemic sclerosis and LS produce increased amounts of connective tissue components, including collagen type I in vitro. Skin biopsies have shown a greater capacity for collagen overproduction and sub-population of fibroblasts with activation of type I collagen expression; these fibroblasts co-localize with inflammatory mononuclear cells that express TGF-β.[9,19] Biopsies of sclerotic lesions also show expression of different isoforms of TGF-β, as well as tissue metalloproteinase-3 (TIMP-3) in sub-populations of fibroblasts cultured from LS lesions.[8–10] TGF-β enhances TIMP-3 expression, and TIMP-3 inhibits breakdown of collagen.[19] It should be noted that three different isoforms of TGF-β (1, 2, and 3) are present in humans; TGF-β1 is the best studied.

Some evidence suggests that the fibrotic response may be driven predominantly by $CD4^+$ T cells. Plasma cells and histiocytes can probably contribute to the stimulation of dermal fibroblasts. Inflammatory cells found in the dermis of scleroderma lesions are primarily T lymphocytes, mainly T helper cells. There is also increased interleukin 2 (IL-2) and IL-4 production.[20] At least in the systemic form of scleroderma, connective tissue growth factor has also been implicated.[11,21,22] A pathogenic role for dermal dendrocytes has also been suggested. The presence of $CD34^+$ and of factor $XIIIa^+$ dermal dendrocytes correlates with active inflammation and sclerosis in LS.[9] The pathogenic role of mast cells in LS has not been clearly elucidated, but mast cells may be a component of sclerodermatous skin, especially in the inflammatory and early stages.[23,24] Mast cell granules contain chemical mediators and proteolytic enzymes that can stimulate fibroblasts and even activate profibrotic cytokines, (i.e., TGF-β); histamine may also stimulate collagen production.[24]

Clinical Findings

There are three main variants of LS: morphea (Fig. 62-1), generalized morphea (see eFig. 62-1.1 in on-line edition), and linear scleroderma (Fig. 62-2, 62-3). Morphea and generalized morphea have a slow and insidious onset and typically affect the trunk.[2] Other less frequent variants include bullous, keloidal, guttate, and subcutaneous morphea (Fig. 62-4). Linear scleroderma is more common in children younger than

▲ **FIGURE 62-1** Morphea: A typical morphea plaque. At an earlier stage, one might see a violaceous border and more edema.

▲ **FIGURE 62-2** Linear scleroderma. **A.** Linear indurated plaques extending from the dorsal aspect of the right hand onto the third digit and involving the proximal and distal interphalangeal joints with contracture. **B.** Older morphea lesions on the foot.

the age of 10 years,[2] with the extremities most commonly affected. With the exception of en coup de sabre (Fig. 62-5; see eFig. 62-5.1 in on-line edition) and progressive facial hemiatrophy, the face and acral areas are typically spared; these areas are usually affected in systemic sclerosis.[2] Patients do not have Raynaud phenomenon or sclerodactyly, and progression to systemic sclerosis is rare.

CUTANEOUS LESIONS ***Morphea.*** Morphea presents with a single or a few circumscribed indurated patches or plaques generally with hypo- or hyperpigmentation (see Fig. 62-1). Early lesions present with edema with or without surrounding erythema. Pain occasionally is present for weeks before becoming clinically apparent. Active lesions can become indurated and maintain an erythematous or violaceous border. With progression, lesions often become whitened or yellow (see Fig. 62-2B), especially centrally. Plaques vary in size from 0.5 to 30 cm.[2] Sub-morphologic variants of morphea include guttate, bullous, keloidal, and morphea profunda (see Figs. 62-4, 62-5).[4] Some authors suggest that lichen sclerosus is a superficial or early form of morphea (see Chap. 63)[25,26]; indeed, the white, atrophic lesions of morphea may resemble lichen sclerosus. Chronic sclerodermoid graft-versus-host disease (see Chap. 28) can have clinically

▲ **FIGURE 62-5** Linear scleroderma, en coup de sabre: Oblique view.

and histologically overlapping features of lichen sclerosus, morphea, and eosinophilic fasciitis (EF), suggesting that these disorders may be part of a spectrum of fibrotic disease.[27,28]

Generalized Morphea. Generalized morphea is a more severe form of morphea characterized by multiple lesions, often showing confluence and involving a larger body surface area (see Fig. 62-2). Some patients may have a subcutaneous form with little surface involvement (see Fig. 62-4).

Linear Scleroderma. Linear scleroderma is characterized by a band-like skin induration often with pigment changes, which may cross joint lines and sometimes leads to contractures (see Fig. 62-2A). This form of LS occurs more commonly in children and on the extremities. The fibrotic process often may extend to the subcutaneous tissue, including fascia and muscle (see Figs. 62-3, 62-5).[2] Joint contractures can be a significant cause of morbidity and deformities (see Fig. 62-2A). In very young children, the process may affect bone growth and disrupt development of tissues. A "pansclerotic" process involving the entire extremity is seen in very severe cases. Pansclerotic morphea in children has been associated with an increased risk of cutaneous squamous cell carcinoma, particularly in ulcerated areas of affected skin.[29,30]

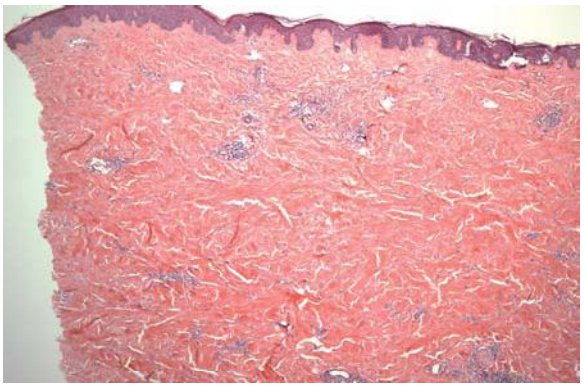
Linear scleroderma occurring on the face may present either as a purplish-brown streak or as a single white, atrophic band running vertically on the forehead, generally known as *en coup de sabre* (see Fig. 62-5, see eFig. 62-5.1 in on-line edition). Progression to involve the scalp is common (see eFig. 62-5.1 in on-line edition). If only the subcutaneous tissue, muscle, and, occasionally, bone are involved, this ipsilateral form

of LS is known as *progressive facial hemiatrophy* or *Parry-Romberg syndrome* (see eFig. 62-5.2 in on-line edition).[2] The extent of skin involvement and the development of facial hemiatrophy are not always directly correlated. Patients affected with facial lesions and Parry-Romberg syndrome fall within a spectrum of disease severity. Mildly affected patients may have only a single linear atrophic band. Severely affected patients may have facial hemiatrophy with loss of subcutaneous tissue, muscle, and bone as well as atrophy of the tongue and salivary glands on the same side. Severely affected patients may also have central nervous system involvement of the meninges and brain with the potential for seizures, headaches, and vision changes.

Eosinophilic Fasciitis. EF, or Shulman syndrome, is a related disorder that presents with the rapid onset of symmetric areas of edema on the extremities (see Chap. 35; see also Deep Morphea in Chap. 68). The condition progresses over several weeks to cutaneous induration and contractures, with features similar to those of subcutaneous forms of LS.[2] Up to 30 percent to 40 percent of patients with EF have lesions indistinguishable from LS.

Atrophoderma of Pasini and Pierini. Atrophoderma of Pasini and Pierini is present in many patients with LS and presents with oval blue to dark brown hyperpigmented atrophic and slightly depressed areas. There is generally no induration or violaceous border in these lesions, in contrast to plaque-type morphea. The borders of the atrophoderma lesions have a "cliff-drop" appearance (see Fig. 65-4). Some consider atrophoderma to be an aborted, superficial form of LS (see Chap. 65).[4,5,31,32]

RELATED PHYSICAL FINDINGS Typically, LS patients have no signs beyond the cutaneous lesions. Initially, before the development of LS, patients may present with arthralgia and, occasionally, frank arthritis. These findings tend to resolve with progression of the cutaneous lesions, but may cause clinicians to consider systemic rheumatologic conditions. Other uncommon findings include fever, regional lymphadenopathy, migraines, abdominal pain, tinnitus, neuralgias, and spina bifida.[2,4] En coup de sabre has been associated with neurologic abnormalities, including seizures, uveitis, and inflammatory lesions of cortical and subcortical regions of the brain. However, there is no recognized internal organ involvement in LS.



▲ **FIGURE 62-6** Morphea, histopathology: Note the squared-off edge of the biopsy specimen with mild superficial and deep inflammatory infiltrate and broadened compact collagen fibers, generally parallel to the epidermis.

LABORATORY ABNORMALITIES ***Serum Autoantibodies.*** Serum autoantibodies have been found with variable frequency in patients with LS. The most commonly found autoantibodies are antinuclear antibodies in up to 46 percent to 80 percent of patients,[5,6,33,34] usually with a homogenous immunofluorescence pattern. With extensive involvement, 36 percent to 53 percent of cases have anti–single stranded DNA and/or antihistone antibodies.[33,35,36] Typically, patients with generalized morphea have a higher frequency of antibody positivity than other subsets of LS, and autoantibodies correlate with a more severe clinical presentation, greater number of lesions, more sclerotic lesions, and a longer duration of clinical course.[2,5]

Other Serum Abnormalities. Blood eosinophilia has been described in 6 percent to 50 percent of patients with LS.[6,34] Levels of eosinophilia appear to correlate with disease activity. Declining levels of eosinophilia may coincide with a decrease in activity of the cutaneous lesions. Elevated immunoglobulins, particularly serum immunoglobulin G levels, have been associated with active, more extensive disease and joint contractures. A positive rheumatoid factor is seen in 26 percent of patients, and the erythrocyte sedimentation rate is elevated in 25 percent.

Histopathology. Early lesions may not have obvious or specific histologic changes. Vacuolization and destruction of endothelial cells with basal lamina reduplication have been reported.[2] Typically, in advanced indurated lesions, one sees a squared-off edge to the biopsy specimen (Fig. 62-6). Superficial and deep inflammatory infiltrates may occasionally be present. Very early lesions may demonstrate an inflammatory infiltrate in the deep dermis and subcutaneous tissue (see eFig 62-6.1 in on-line edition). Lymphocytes, macrophages, plasma cells, eosinophils, and mast cells are also seen. Deposition of glycosaminoglycans may be detected in the early stages of LS, particularly if care is taken to preserve this matrix component during histologic processing.[40]

Differential Diagnosis (Box 62-1)

Complications

Subcutaneous and muscle tissue atrophy and joint contractures are mainly seen in linear scleroderma (see Figs. 62-2,

Box 62-1

Differential Diagnosis of Morphea

Most Likely
- Systemic sclerosis (scleroderma)
- Eosinophilic fasciitis

Consider
- Lichen sclerosus
- Lupus profundus
- Connective tissue nevi
- Morpheaform basal cell carcinoma
- Toxic oil syndrome
- Chronic graft-versus-host
- Lipodermatosclerosis

Always Rule Out
- Lyme disease, acrodermatitis chronica atrophicans
- Phenylketonuria
- Porphyria cutanea tarda
- POEMS syndrome

POEMS = *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes.

62-3), generalized morphea (see eFig. 62-1.1 in on-line edition), and subcutaneous morphea (morphea profunda), and can cause significant impairment of mobility. Contractures are frequently seen in linear scleroderma involving limbs and crossing joint lines (see Fig. 62-2A). Children are more commonly affected by linear scleroderma than adults. In rare and severe cases, pansclerotic morphea may require amputation of the involved limbs because of their impaired growth. Patients with linear craniofacial involvement (see Fig. 62-5), such as en coup de sabre and facial hemiatrophy, may have neurologic, ophthalmologic, and oral abnormalities.[2,6] Severe cases of LS characterized by hyper- or hypopigmentation, contractures, and underlying tissue atrophy can be devastating. These complications lead to functional, cosmetic, and psychological difficulties.[2,5]

Prognosis and Clinical Course

In spite of the common presence of serum autoantibodies, LS typically does not have a recognized systemic involvement, although a rare overlap with other connective tissue disorders has been reported. Most cases of LS are self-limited, with clinical activity apparent for an average of 3 to 5 years. Some patients may have re-activation of apparently inactive lesions. In up to 13 percent of patients with linear scleroderma, one sees re-activation after several years of remission. En coup de sabre may have an insidious course lasting for decades. It may be that LS remains a chronic process with a low level of activity over many years. Slight atrophy with or without hyperpigmentation may be the only persistent sign of disease.

Treatment

In many cases, LS lesions become inactive spontaneously; however, more severe cases can cause irreversible fibrosis/sclerosis of the skin and subcutaneous tissues. Treatment is directed at the inflammatory component, cytokine release, and activation and collagen deposition. Many therapies have been used in the treatment of LS with variable success. Topical and systemic steroids, oral and topical vitamin D analogues, methotrexate, cyclophosphamide, azathioprine, hydroxychloroquine, intralesional interferon-γ, penicillin and D-penicillamine have all been tried.[41–47] Physical therapy is of the greatest importance in patients with contractures to preserve or improve limb function. Treatments that have been reported to be successful include D-penicillamine,[45] topical tacrolimus under occlusion,[48] oral calcitriol,[47] topical calcipotriene,[47–49] methotrexate alone[42] or combined with pulsed corticosteroids,[44] topical imiquimod,[50] topical tretinoin with ammonium lactate,[51] and N-(3′, 4-dimethoxycinnamoyl) anthralinic acid—an antiallergy medication that inhibits passive cutaneous anaphylaxis.[52] In pediatric cases with impaired growth of the affected extremity, timely surgical intervention and "stapling" of the epiphyseal plates of the normal side may be effective. This will result in slower, but continued, growth of the affected extremity and may lead to a lesser degree of limb disparity.

PHOTOTHERAPY Several studies have demonstrated marked improvement in a majority of LS patients using psoralen and ultraviolet A light, broad band ultraviolet A (UVA), or UVAI phototherapy.[3,55–60]

PRACTICAL APPROACH In the absence of truly randomized and prospective clinical trials, the approach to patients is often highly individualized. For limited involvement with one or few morphea lesions, one can use topical treatments such as calcipotriene, tacrolimus, retinoids, or no treatment at all. On the other hand, lesions of en coup de sabre can lead to considerable disfigurement. Our approach to those facial lesions has been the use of either hydroxychloroquine or perhaps methotrexate in combination with small doses (5 to 10 mg) of systemic corticosteroids. For more generalized involvement, we usually use phototherapy. If that approach is not successful, or if there is substantial subcutaneous involvement, a useful medication is methotrexate. Beyond these approaches, one is left with even more anecdotal experience. D-penicillamine, cyclosporine, and other immunosuppressive agents have been used.

CHAPTER 63

Lichen Sclerosus

Ulrich R. Hengge

Lichen sclerosus (LS) is a chronic inflammatory dermatosis of the anogenital area that affects quality of life due to the severe itching. LS may also present with extragenital manifestations that are generally non-pruritic. Of note, vulvar disease seems to have an increased risk of squamous cell carcinoma, but the role of additional co-factors (e.g., human papillomavirus infection or prior radiotherapy) has not been defined.

EPIDEMIOLOGY

The incidence of LS has not been precisely determined. It has been estimated to be in the order of 14 per 100,000 persons per year.[1] LS is more prevalent in females, accounting for a 5:1 gender ratio. It preferentially affects women in the fifth or sixth decade of life and children younger than the age of 10 years.[1,2] Up to 15 percent of LS cases occur in children, particularly in girls, and one study reported a prevalence of 1 in 900 premenarchal girls.[3] A 0.07 percent incidence in males has recently been determined in a study of 153,432 male soldiers.[4] Among blacks and Hispanics, the incidence in this group was 1.06 percent, whereas the

LICHEN SCLEROSUS AT A GLANCE

- Infrequent chronic inflammatory dermatosis with anogenital and extragenital manifestations.
- Preferentially affects women in the fifth or sixth decade of life and children younger than the age of 10 years; gender ratio 5:1 female–male.
- Antibodies to extracellular matrix protein-1 and T cells with receptor rearrangement point to an autoimmune pathogenesis.
- Anogenital manifestations cause severe discomfort (pruritus, dyspareunia, dysuria, and painful defecation) and present with polygonal papules and porcelain-white plaques, erosions, and various degrees of sclerosis.
- Vulvar lichen sclerosus is associated with an increased risk of squamous cell carcinoma; the role of human papillomavirus infection or prior radiotherapy remains to be elucidated.
- Potent topical corticosteroids and skin care are the most successful therapeutics; calcineurin antagonists have also recently demonstrated benefit.
- Interdisciplinary management is essential for long-term control.

incidence was only 0.051 percent in white soldiers.[4] LS seems to be a prominent cause of phimosis; in one study, 14 percent of adolescent boys had LS, whereas 40 percent of phimosis cases in adult men were associated with LS.[5] Similarly, a recent study of foreskins examined after therapeutic circumcision for phimosis confirmed many cases of unrecognized LS.[6] As genital LS in males is almost exclusively seen in uncircumcised men, the rate of circumcision in a given population has a strong impact on the occurrence of the disease.

ETIOLOGY AND PATHOGENESIS

The cause of LS is unknown. There is no genetic predisposition.[7] Evidence for the presumed infectious cause, such as acid-fast rods, spirochetes, or *Borrelia*, has not been found.[7] Serologic and clinical evidence of thyroid disease, alopecia areata, pernicious anemia, and vitiligo suggested an association with LS. Extragenital LS is commonly seen in association with plaque-type morphea, and some authors have suggested a common pathomechanism. Recently, low-titer autoantibodies against the extracellular matrix protein-1 (ECM-1) and collagen XVII have been identified in 67 percent of LS.[8,9] ECM-1 (see Chap. 137) may be involved in basement membrane and interstitial collagenous fiber assembly and growth-factor binding,[10] and may also regulate blood vessel function.[11] Local irritation also seems to play a role in some cases. The disturbed function of fibroblasts with increased production of collagen has been demonstrated in LS.[12,13]

CLINICAL FINDINGS

Cutaneous Lesions

Polygonal papules and porcelain-white plaques with atrophic fragile skin, fissures, telangiectasias, purpura, erythema, erosions, and different degrees of sclerosis are present in the anogenital area (Fig. 63-1A to F); sometimes the classical figure-8 pattern of the vulva and anus may be observed (see Fig. 63-1E). Blisters (occasionally hemorrhagic) may develop when the lichenoid infiltrate separates epidermis from the sclerotic dermis. The size of LS lesions may vary from a few millimeters to large portions of the trunk. Anogenital LS frequently causes intractable itching and soreness, dyspareunia, dysuria, discomfort with defecation, or genital bleeding and, with time, may lead to destructive scarring (see Fig. 63-1F). Gradual obliteration or synechiae of the labia minora and clitoris, as well as stenosis of the introitus, may also result (see Chap. 76). Male genital LS is usually confined to the glans penis, prepuce, or foreskin remnants (see Fig. 63-1A to C). Penile shaft involvement is less common, whereas scrotal involvement is rare. Many male genital LS cases are simply diagnosed as phimosis. In severe cases, erections may become painful (see Chap. 75). Extragenital manifestations typically affect the thigh, the neck, and trunk; lesions are usually asymptomatic (Fig. 63-2). Rarely the oral mucosa may also be involved.

Related Physical Findings

Except for the association with autoimmune thyroid disease, alopecia areata, pernicious anemia, morphea, and vitiligo, which should be ruled out, no additional related findings have been reported. In particular, genital infections by herpes simplex virus or *Candida* do not seem to be increased in LS patients.

LABORATORY TESTS

Histopathology

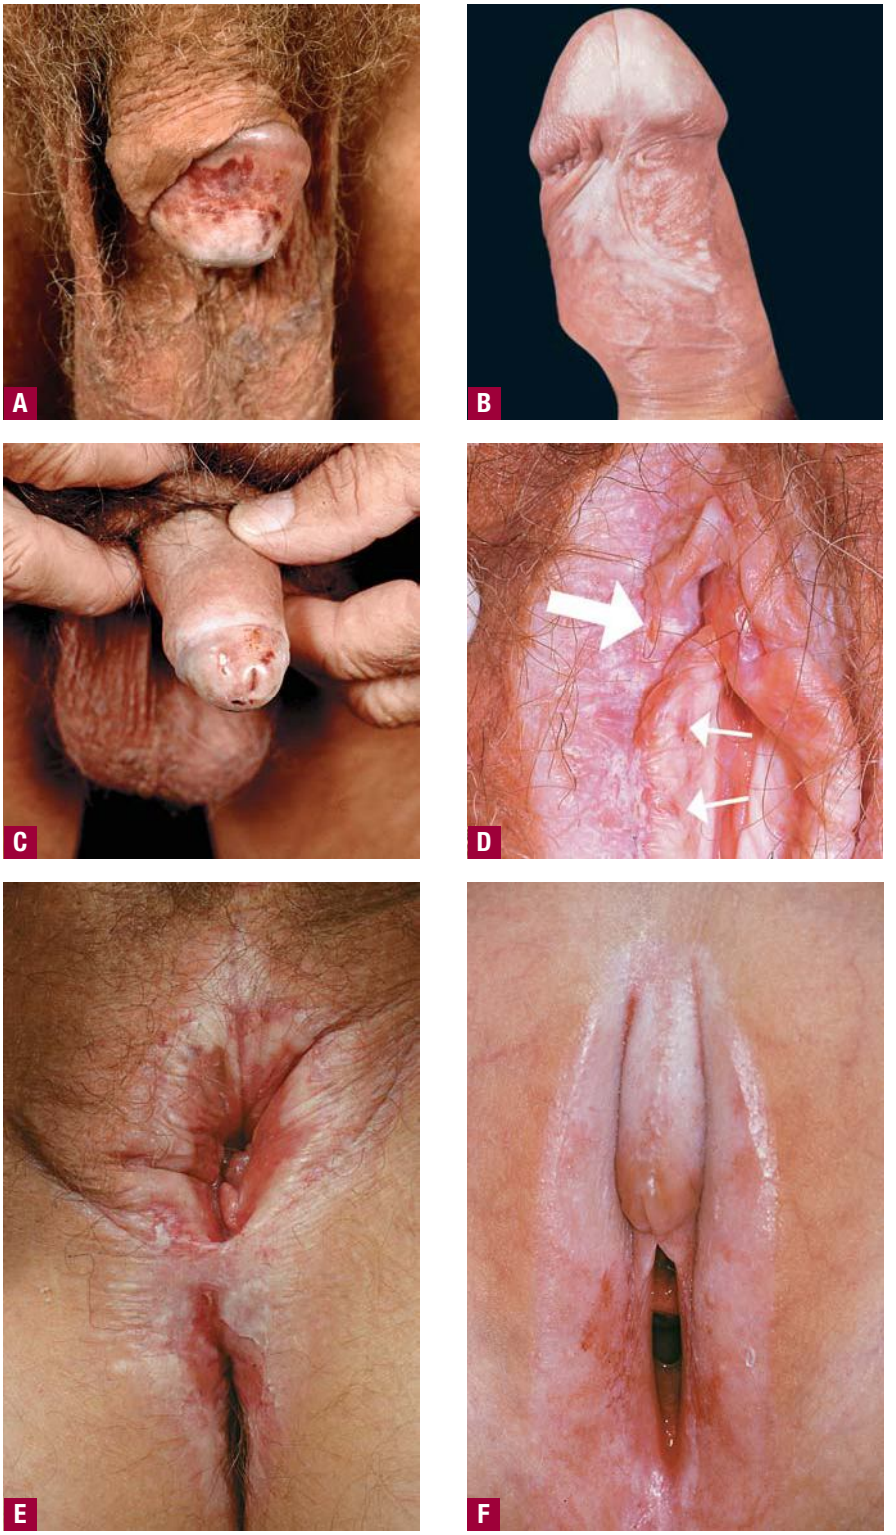
Classical LS shows an atrophic epidermis and a lichenoid infiltrate at the dermal-epidermal junction.[14] Papillary edema is usually seen in early LS but is gradually replaced by fibrosis with homogenization of acid mucopolysaccharides as the lesion matures (Fig. 63-3). The lymphocytic infiltrate in LS contains abundant T cells, B cells, and antigen-presenting dendritic cells that are major histocompatibility complex class II^+, $CD8^+$, and $CD57^+$.[15,16] A monoclonal T-cell receptor γ-chain rearrangement has alluded to the existence of an LS antigen, potentially the ECM-1 protein, which is also recognized by the recently described autoantibodies.[8,17] Epidermal hyperplasia and/or dysplasia associated with LS on vulvar specimens are associated with an increased risk of malignant transformation, especially in conjunction with infection by high-risk papillomaviruses.

Special Tests

Imaging studies are only needed in special situations (e.g., urinary obstruction secondary to stenosing genital LS). High-resolution ultrasound is occasionally used to document the depth of sclerosis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

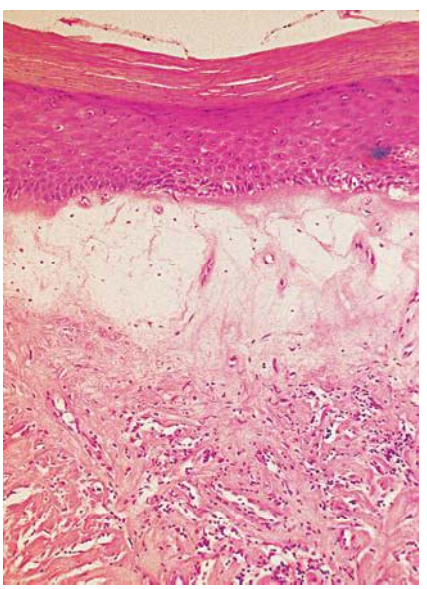
A skin punch biopsy of a mature lesion will confirm the diagnosis if the diagnosis is not obvious by clinical examination. ECM-1 autoantibodies may be detected by specialized laboratories; a commercial enzyme-linked immunosorbent assay has recently become available.[18] Despite the described association with autoimmune diseases, an autoimmune workup (e.g., anti-nuclear antibody, parietal cell antibody, vitamin B_{12} levels, thyroid function tests) is not generally recommended due to their relatively low occurrence.[19] For the same reason, *Borrelia* antibody titers should not be analyzed, as they are not associated with LS.[20] To exclude squamous cell carcinoma, repetitive biopsies may be indicated.



▲ **FIGURE 63-1** **A.** Early sclerosis and significant hemorrhage on the glans in early lichen sclerosus. **B.** Sclerosis of the frenulum and increased vulnerability with bleeding upon sexual intercourse. **C.** Significant sclerosis of the glans and conglutination with the preputium in advanced lichen sclerosus. Note narrowing of the urethral orifice and hemorrhage. **D.** In addition to the well-demarcated white vulvar plaque that is classic for lichen sclerosus, the waxy and crinkled texture, purpura (*small arrows*), and erosions (*large arrow*) are diagnostic. **E.** Sclerotic vulva with disappearance of the smaller labia and shrinkage of the introitus. Significant erythema and erosions are seen on the vulva and the anus in a figure-8 configuration. The patient complained of severe pruritus and dyspareunia. **F.** Erosive, sclerotic vulva in an 8-year-old girl.

▲ **FIGURE 63-2** Extragenital lichen sclerosus with confluent whitish papules and plaques on the skin over the thoracic and lumbar spine.

The differential diagnosis of LS and localized scleroderma (morphea) may be difficult (Box 63-1; see Fig. 63-2). Clinically, morphea may be confused with extragenital LS. Morphea represents a circumscribed connective tissue disease with a number of different presentations. Typical early plaque-type lesions show a lilac ring with progressive central induration and whitening and peripheral hyperpigmentation (see Chap. 62). Histologically, early morphea presents as a dense lymphocytic, superficial, and deep perivascular infiltrate with degeneration of collagen fibers. In later stages, inflammation is replaced by dermal fibrosis much like the changes seen in LS. Patients have been described with lesions typical of



▲ **FIGURE 63-3** Hyperkeratotic epithelium without rete ledges and basal degeneration of keratinocytes. Collagen fibers are homogenized in the papillary dermis, and a lichenoid lymphocytic infiltrate is present. The dermal vessels are dilated.

Box 63-1

Differential Diagnosis of Lichen Sclerosus

GENITAL MANIFESTATIONS

Consider

- Balanitis plasmacellularis (Zoon disease)
- Child abuse (sexual)
- Complications of dermatologic laser surgery
- Contact dermatitis, including excessive genital hygiene
- Lichen planus
- Lichen simplex chronicus
- Vitiligo

Rule Out

- Cicatricial (scarring) pemphigoid
- Erythroplasia of Queyrat (Bowen disease)
- Leukoplakia
- Squamous cell carcinoma
- Paget disease

EXTRAGENITAL MANIFESTATIONS

Consider

- Anetoderma
- Atrophoderma of Pasini and Pierini
- Idiopathic guttate hypomelanosis
- Lipoid proteinosis (mild forms, see Chap. 137)
- Lichen nitidus
- Lichen planus
- Morphea
- Pinta
- Tinea versicolor

Rule Out

- Discoid lupus erythematosus
- Graft-versus-host disease (scleroderma-like)
- Extramammary Paget disease
- Squamous cell carcinoma

both plaque-type morphea and the chalky white, atrophic plaques of LS, suggesting that morphea and LS may share a common pathomechanism.[21] Anti-nuclear antibodies may be positive in either morphea or LS.

Constipation is a common complication in children with anogenital LS.[22] The associated purpura and discoloration often raise concern about child abuse, especially if LS is not recognized (see Chap. 105). LS in children has occasionally been associated with a perineal pyramidal protrusion, a common lesion that can be confused with condyloma and is also associated with constipation. This association further (erroneously) increases the suspicion of sexual abuse.[23,24] It should be noted, however, that LS and child abuse may co-exist[25] and that some cases of LS have been linked with trauma of the anogenital region (see Chap. 105). See Box 63-2 for pitfalls in the diagnosis of LS.

Box 63-2

Pitfalls in the Diagnosis of Lichen Sclerosus

- Wrong/incomplete diagnosis in the case of squamous cell carcinoma.
- Lichen sclerosus, especially when bullous, hemorrhagic, or erosive; may be confused with child abuse.
- Inappropriate surveillance for steroid adverse effects.
- Irritant dermatitis due to overwashing of the anogenital area may imitate lichen sclerosus and facilitate the occurrence of contact dermatitis.

COMPLICATIONS

Besides dyspareunia, urinary obstruction, constipation, secondary infection related to ulceration, and steroid use, squamous cell carcinoma represents the main complication in females (Fig. 63-4). The lifetime risk of developing squamous cell cancer as a complication of long-standing LS has been estimated in the order of 4 percent to 6 percent.[1,26] Age, long duration of LS, human papillomavirus infection, and evidence of hyperplastic changes represent significant risk factors.[27,28] In males, painful erections and urinary obstruction represent the most frequent complications.

PROGNOSIS AND CLINICAL COURSE

The prognosis of LS is good for most anogenital cases, especially for those in prepubertal children that may resolve spontaneously or may be healed after treatment with ultrapotent topical steroids.[29] The disease is usually self-limiting, but requires treatment due to the severity of patient discomfort. Recalcitrant chronic LS causing erosions and progressive scarring may result in severe sexual dysfunction. Cosmetic improvement for extragenital cases and for chronic atrophic genital disease is rather poor.

TREATMENT

Various attempts to treat LS have been undertaken. The single most effective treatment of LS is ultrapotent topical corticosteroids such as clobetasol.[17,29–38] However, there is no systematic trial to support this common practice. Due to corticosteroid adverse effects, the treatment period with ultrapotent steroids should be limited, generally to less than 4 weeks. Treatment should be continued, when necessary, with less potent corticosteroids or calcineurin inhibitors (see below).

▲ **FIGURE 63-4** **A.** A 1.5-cm, sharply demarcated ulcer of long-standing lichen sclerosus on the right major labium. **B.** Histology reveals squamous cell carcinoma.

Case series using topical tacrolimus and pimecrolimus have shown clinical effectiveness.[40–44] Although many of the effects of topical tacrolimus parallel those of corticosteroids,[45] adverse effects such as atrophy, telangiectasias, and pigment changes do not occur. A recent multicenter, phase II trial has assessed the safety and efficacy of twice-daily application of tacrolimus ointment 0.1 percent in 84 patients (49 women, 32 men, and 3 girls) with long-standing LS (mean duration, 5.8 years),

with a follow-up period of 18 months.[46] Clearance of active LS was reached by 42.9 percent of patients, with at least 50 percent improvement in an additional 34.3 percent of patients. However, the duration of treatment to achieve an optimal response was up to 24 weeks.

Systemic therapy with retinoids, including isotretinoin, etretinate, and acitretin and oral tacrolimus, have been useful in small trials. Systemic antibiotics against borreliosis and penicillamine have not proved effective.

Destructive surgical therapies, such as cryotherapy, the tissue-vaporizing carbon dioxide lasers, and non-ablative lasers such as the pulsed dye and Erb: YAG lasers, have been reported to work in LS but should only be used with caution. Vulvectomy should be limited to cases in which squamous cell carcinoma has been detected.

Female LS patients should be particularly monitored for any sign of secondary genital malignancy. Prepubertal LS in girls may resolve spontaneously; however, some of these patients may eventually suffer from vulvodynia in adulthood. In case of LS-associated dyspareunia that interferes with sexual activity, the use of topical anesthetics should be considered.

Circumcision will generally resolve male genital LS and the associated phimosis, although potent topical steroids may obviate the need for surgery. Asymptomatic extragenital LS usually requires no treatment other than cover makeup in selected cases.

PREVENTION

No truly preventive measures of LS have been reported. An interdisciplinary management is essential for the long-term control of LS. Specialists from gynecology, urology, pediatrics, and psychosomatic medicine should be involved in patient care and collaborate to prevent significant complications, including the monitoring for squamous cell cancer and corticosteroid adverse events. It has also been helpful to circulate information via patient organizations for LS.

CHAPTER 64

Dermal Hypertrophies

Mandy Harting
M. John Hicks
Moise L. Levy

DERMAL HYPERTROPHIES AND BENIGN DERMAL TUMORS

Dermal tumors and proliferations represent an often encountered and clinically bewildering group of disorders. This chapter reviews several of the benign dermal tumors. Some of these present clinically in a fashion that can offer clues diagnostically. Histopathology is key to the ultimate diagnosis and proper management of several of these conditions. Malignant fibrous tumors of the dermis are discussed in Chap. 125.

FIBROMATOSES

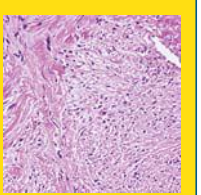
Fibromatoses are proliferations composed of fibrous tissue, fibroblastic cells, or spindled stromal cells with varying degrees of cellularity, and often exhibiting myofibroblastic or fibroblastic differentiation. Although on occasion the fibromatoses of childhood may spontaneously regress, those occurring in adults usually behave much more aggressively. Generally, fibromatoses are considered benign conditions; however, rare malignant transformation occurs in some tumors.

CHILDHOOD FIBROMATOSES

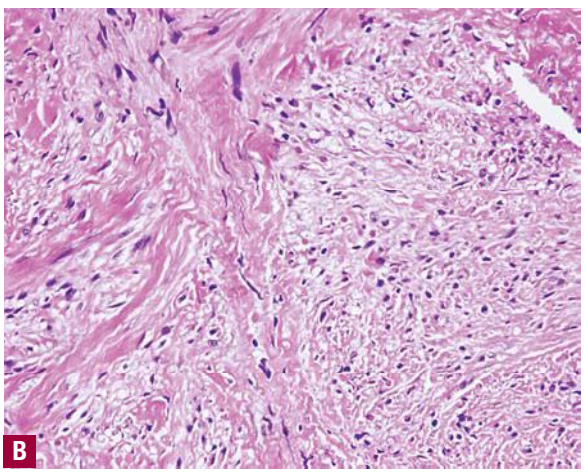
Solitary Lesions

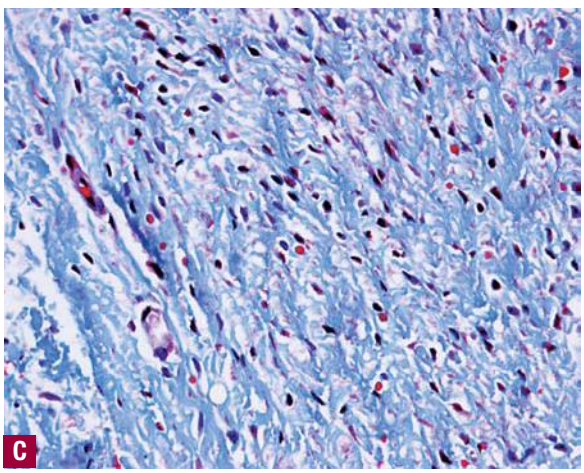
FIBROMATOSIS COLLI (STERNOMASTOID TUMOR OF INFANCY) Fibromatosis colli (sternomastoid tumor of infancy) is a self-limiting disorder that is characterized by a benign proliferation of fibroblasts in the lower one-third of the sternocleidomastoid muscle. Fibromatosis colli usually appears in the first few weeks of life and can grow rapidly. This condition may clinically and radiographically mimic other tumors, such as rhabdomyosarcoma or neuroblastoma, due to its rapid growth and marked expansion of the sternocleidomastoid.[1] It is the most common cause of neonatal torticollis,[2] although other causes of tor-

DERMAL HYPERTROPHIES AT A GLANCE



- There are childhood and adult variants of dermal hypertrophies, which can be indolent or aggressive in their behavior.
- Desmoid tumors are locally aggressive and infiltrative, deep-seated tumors characterized by high recurrence rates after surgical excision.
- Hypertrophic scars and keloids remain very common dermal hypertrophies, which are often difficult in their management.
- Other dermal hypertrophies include solitary lesions, such as dermatofibromas and acrochordons, hamartomas, and connective tissue nevi.





◀ **FIGURE 64-1** **A.** Well-defined pink nodule of infantile digital fibromatosis. Usually the third to fifth digits are affected; here, the tumor is found on the second digit of an infant. **B.** Infantile digital fibromatosis possesses poorly circumscribed interlacing bundles of myofibroblasts embedded in a modest background of collagen (hematoxylin and eosin 100× magnification A). **C.** The defining characteristic is densely eosinophilic, cytoplasmic inclusion bodies in fibroblasts that also stain red with Masson trichrome (100× magnification).

ticollis, such as vertebral anomalies, ocular muscle disorders, Sandifer syndrome, and superficial and deep cervical infections, must be considered.[1] This condition usually resolves within the first year of life.[1]

Invasive diagnostic and therapeutic interventions are not necessary, and excisional biopsy should be reserved for cases in which malignancy is highly suspected.[3] Fine-needle aspiration reveals clusters of benign, spindled, plump fibroblasts with ovoid to elongated nuclei. It is the preferred technique in diagnosing fibromatosis colli.[2]

INFANTILE DIGITAL FIBROMATOSIS (INCLUSION BODY FIBROMATOSIS, REYE TUMOR) Infantile digital fibromatosis was first described by Reye in 1965 as a rare form of superficial juvenile fibromatosis presenting as an asymptomatic, flesh-colored, firm nodule on the fingers and toes, primarily in infants and less commonly in children. This tumor is a benign fibroblastic proliferation that appears in the first year of life and may be present at birth in one-third of cases.[4] The tumor almost always affects the third to fifth digits, rarely the second digits, and never the thumb or hallux (Fig. 64-1A).

Histologically, poorly circumscribed, interlacing bundles of myofibroblasts are observed. The pathognomonic finding is eosinophilic, paranuclear inclusion bodies in the fibroblasts, which stain red with Masson trichrome stain and purple with phosphotungstic acid-hematoxylin (see Fig. 64-1B, C).[5] These inclusions are actin filaments arranged in a whorled pattern on electron microscopic study, and they immunoreact with smooth muscle and vimentin. At times, these inclusions may be sparse, but their presence may eliminate infantile myofibromatosis and congenital infantile fibrosarcoma from the differential diagnosis. It should also be realized that digital fibromas may comprise one component of a syndrome. Digital fibromas have occasionally been associated with facial pigmentary dysplasia, focal dermal hypoplasia, metacarpal and metatarsal disorganization, and limb malformations.[6,7]

At one time, infantile digital fibromatosis was considered a potentially malignant disease. However, malignant transformation or metastatic disease has never been reported to date; thus, conservative therapy with simple surgical excision of the nodule only is recommended.[8] Although spontaneous regression over years has been observed in some cases, surgical intervention has been used because residual deformities of the digit and contractures can occur with larger lesions.[4] Up to 60 percent of cases recur even after wide local excision.[8] Intralesional fluorouracil has been used with good clinical outcome in one case.[8] Some have used intralesional triamcinolone for recurrences after shave biopsy, with good results.

CALCIFYING APONEUROTIC FIBROMA Calcifying aponeurotic fibroma is an uncommon, benign, fibrous tumor that was first described by Keasbey in 1953.[9] It is most commonly found on the palms and soles of children and young adults. However, it can present in any area that is closely related to aponeuroses, such as the neck, forearm, popliteal fossa, lower back, and thigh. It is a very slow growing, deep-seated firm proliferation that presents as an asymptomatic infiltrative soft tissue mass, usually measuring less than 3 cm in diameter.[10] Its peak incidence is between the ages of 8 and 14.[11]

Surgical excision is the current recommendation. However, 50 percent of the tumors recur locally, usually within 3 years of diagnosis, and rare cases of malignant transformation have been reported.[11,12] Due to calcifications, calcific stippling may be seen by x-ray. Because of the tendency to recur, magnetic resonance imaging has been used to deter-

mine the extent of the tumor and best surgical strategy.[13] Local recurrence is more common in children younger than 5 years of age.

Multifocal Lesions

AGGRESSIVE INFANTILE FIBROMATOSIS Aggressive infantile fibromatosis presents as rapidly growing nodules on the trunk, with a high potential for local invasiveness. This tumor rarely spontaneously regresses.[14] Histologically, the tumor is variable, including an immature mesenchymal pattern, a collagenous pattern, and a desmoid pattern. Distant metastasis rarely occurs. Whether this represents metastatic disease versus multifocal lesions is difficult to determine from a clinical and radiographic standpoint. Cytogenic and molecular pathology analyses are important.

INFANTILE MYOFIBROMATOSIS First described by Enzinger in 1981, infantile myofibromatosis is the most frequent fibromatosis in childhood and consists of a benign proliferation of fibroblasts and myofibroblasts.[16] Solitary or multiple nodules involving the skin, striated muscles, bones, and viscera may be seen. Three types exist: solitary, multicentric, and generalized. Patients that have generalized disease often have visceral involvement, and may have a 75 percent mortality rate.[17,18] Although most cases are sporadic, a familial pattern of inheritance has been reported in few cases.[17]

Extensive surgical therapy is reserved for patients with multicentric or generalized disease because solitary lesions may spontaneously regress. Close clinical follow-up of solitary lesions with excision when they affect function or are of a cosmetic concern would be indicated. Due to the increased mortality rate of patients with multicentric and generalized disease, chemotherapy and radiotherapy have been used in these cases.[17]

JUVENILE HYALINE FIBROMATOSIS Juvenile hyaline fibromatosis (JHF) was first reported by Murray in 1873 as molluscum fibrosum, but the current name in use was provided by Kitano in 1976.[19] It is a rare, autosomal recessive condition, characterized by the onset, at ages 2 months to 4 years, of subcutaneous, pearly papules and firm, large nodules that progressively enlarge and tend to ulcerate.[20] Recently, a defect on chromosome 4q21 associated with the locus of the capillary morphogenesis gene-2 (CMG2) has been demonstrated. This gene encodes a protein that is upregulated during capillary formation. The resulting protein binds to laminin and collagen IV via von Willebrand's factor type A domain. CMG2 also acts as a cellular receptor for anthrax toxin. How absence of CMG2 protein leads to JHF is not clear, but perturbation of basement–membrane matrix assembly likely contributes to the characteristic perivascular hyaline deposition.[6,7,19,20]

The most commonly affected areas include the nose, chin, ears, scalp, back, and knees.[19] Patients tend to have gingival hypertrophy, which can result in periodontal disease and caries due to problems maintaining adequate oral hygiene. Deposition of hyaline material is found in various organs, including the skin.[20,21] Progressive joint contractures, osteolysis, and muscular weakness can result in severe debilitation.[19]

Histologically, cords of spindled myofibroblasts, often with cytoplasmic vacuoles, occur in hyalinized and chondroid stroma. Calcospherules have been demonstrated and are helpful diagnostic markers.[19] Ultrastructural analysis shows amorphous, fine fibrillar material with the banding pattern of type VI collagen.

The differential diagnosis of JHF includes infantile systemic hyalinosis (ISH), which is now known to be allelic. Currently, no widely accepted effective treatment exists for JHF or ISH. Surgical excision is often not feasible due to the number and size of the tumors, and anesthesia can be complicated because of the oral and dental issues. Administration of interferon-α 2b over 2 years led to significant improvement in an 8-year-old patient with JHF.[20]

FIBROMATOSES OF ADULT ONSET

Dupuytren Contracture (Palmar Fibromatosis)

Dupuytren contracture (palmar fibromatosis) is a fibroproliferative disease characterized by bilateral, progressive fibrosis of the palmar fascia, most commonly presenting as nodules over the fourth and fifth metacarpal head. Joint contractures and flexion deformities of the fingers soon follow. Significant risk factors for development of Dupuytren contracture include old age, male sex (three- to fourfold increase), white northern European ancestry, family history, seizures, alcohol-induced liver disease, trauma, smoking, and diabetes mellitus.[22–24] This condition rarely occurs before age 30 years and is very rare in children. Ledderhose disease is characterized by plantar fibrosis over the medial sole of the foot and is identical to Dupuytren disease histologically.[23]

Histologically, the palmar aponeurosis and adipose tissue demonstrate nodules of fibroblasts in a dense reticulin network. In older lesions, thick, acellular collagen bundles predominate.[25]

Patients may gain significant functional benefit from surgical correction of the deformity.[22] Recurrence is more common in patients with greater initial deformity, but less common if good surgical correction is achieved and postoperative rehabilitation provided.[22,29]

Peyronie Disease (Induratio Penis Plastica, Penile Fibromatosis)

Fibrosis of the fibrous septa between the corpus spongiosum and the corpora cavernosa along the dorsum of the penis is termed *Peyronie disease*. This condition is often associated with Dupuytren disease (up to 4 percent of cases), and risk factors include genetic predisposition, trauma to the penis, and systemic vascular diseases. Smoking and alcohol consumption also seem to have some role in the development.[30] The histology is very similar, if not identical, to that of Dupuytren contracture.

Over several years, many patients have spontaneous regression of their lesions.[31] However, some new surgical corrective techniques have proved safe and beneficial (e.g., corporeal plication, which consists of placing longitudinal plication sutures of braided polyester on the opposing side of curvature until it is corrected during artificially induced erection).[32]

Knuckle Pads

Knuckle pads are circumscribed, hyperkeratotic, or fibrous growths over the dorsal aspects of the interphalangeal joints.[33] In children, these tend to be reactive and primarily epidermal. The association of knuckle pads with leukonychia, sensorineural deafness, and, sometimes, palmoplantar keratoderma, is seen in Bart-Pumphrey syndrome and results from mutations in GJB2, which encodes connexin 26. Adult cases may show dermal involvement, and many patients have co-existing fibromatosis of the palmar, plantar, or penile aponeurosis or fascia.[34] Knuckle pads can sometimes be difficult to distinguish from synovitis, but ultrasound can quickly identify these su-

perficial fibrous growths.[35] Histologically, these lesions are very similar to Dupuytren disease. False knuckle pads are due to repetitive mechanical trauma or factitious injury seen in bulimic patients. Affected individuals show these characteristic, self-induced lesions as on the dorsal aspect of the second and third fingers because of chronic abrasion of the skin against the maxillary incisors during forced emesis.

Pachydermodactyly

Pachydermodactyly is a rare form of benign digital fibromatosis consisting of asymptomatic, circumscribed swelling of the fingers. Currently, there are only 62 reported cases in the literature. Clinically, it appears as a painless enlargement of the tissues surrounding the proximal interphalangeal joints of the second to fifth fingers. It primarily affects adolescent males, with a male-female ratio of 5:1.

Desmoid Tumor

Desmoid tumors, also known as *deep* or *aggressive fibromatoses*, are low-grade clonal mesenchymal neoplasms that fall within the spectrum of a variety of benign musculoaponeurotic fibromatoses. These poorly circumscribed tumors are deep-seated, characterized by an infiltrative growth pattern and locally recur, but lack the ability to metastasize. These tumors have a mutation in the adenomatous polyposis coli (APC) gene (5q21) and are associated with familial adenomatous polyposis (FAP) syndrome and Gardner syndrome.[6,7] There may be an estrogenic influence with these tumors that is noted during pregnancy.[37] Injury precedes some cases.[38]

Desmoid tumors are usually categorized as extra-abdominal or intra-abdominal tumors. The extra-abdominal tumors are often located in the area of the shoulder and pelvic girdle or chest and neck wall (Fig. 64-2). These tumors are most often sporadic.[41] Intra-abdominal desmoids have been associated in 10 percent to 15 percent of patients with FAP and Gardner syndrome, with the latter usually presenting as retroperitoneal tumors.[37,39]

Devoid of metastatic potential, they tend to form large, infiltrative masses that recur repeatedly.[40] Rarely, desmoid tumors transform into classic fibrosarcomas.[41]

Histologically, these are poorly circumscribed proliferations of mature fibrous tissue arising from a musculoaponeurosis. There is a paucity of cellularity with collagenous stroma predominating. When compared with classic fibrosarcomas, desmoid tumors are more monomorphous and less cellular.

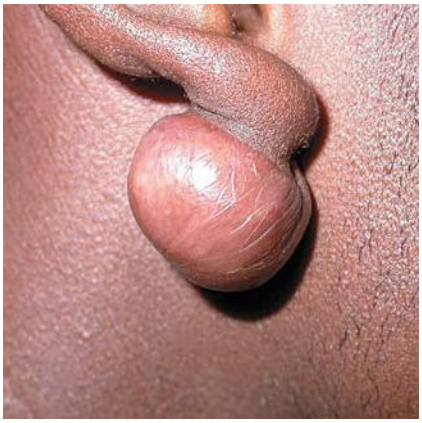
▲ **FIGURE 64-2** Desmoid tumors involving upper chest and epigastric region. These represent recurrences after multiple surgical interventions. This patient also had intra-abdominal desmoid tumors.

Due to the aggressive and infiltrative behavior of these tumors, treatment can be very difficult. Although surgery is widely accepted as the first-line treatment for extra-abdominal and abdominal wall tumors, complete surgical excision is difficult to achieve, and recurrences occur in 25 percent to 65 percent of cases.[39]

REACTIVE AND DEGENERATIVE FIBROUS LESIONS

Hypertrophic Scars and Keloids

Hypertrophic scars and keloids result from the uncontrolled synthesis and excessive deposition of collagen at sites of prior dermal injury and wound repair. They often occur after local skin trauma (such as laceration, tattoo, burn, injection, ear piercing, vaccination, or surgery) or inflammatory skin disorders (such as acne, bites, or abscesses). A keloid extends beyond the borders of the original wound, does not regress spontaneously, grows in a pseudotumor fashion with distortion of the lesion, and tends to recur after excision (Fig. 64-3). Hypertrophic scars, in contrast, remain confined to the borders of the original wound and most of the time retain their shape. Hypertrophic scars and keloids show a predilection for areas with increased tension, such as the shoulders, sternum, mandible, and arms. They are more common in Asians and dark-skinned races.[45] Hypertrophic scars can occur at any age, whereas keloids commonly occur in the third decade. Keloidal growth can be triggered by pregnancy.



▲ **FIGURE 64-3** Keloid. Firm, non-tender erythematous nodule on the ear that developed after ear-piercing.

Keloids appear as well-circumscribed pink to purple firm nodules (see Fig. 64-3) or plaques with a smooth, but irregular border (Fig. 64-4). Compared with hypertrophic scars, these nodules are often painful and hyperesthetic. Ulceration can occur due to the thin overlying epidermis, and hyperpigmentation is common.

Although historically hypertrophic scars and keloids have been thought of as different stages of the same wound repair process, new evidence suggests that they may be two separate entities. This new perspective is based on differences observed in behavior of the lesion, morphology, cell biology, and immunohistochemically.[46] In early scars,

▲ **FIGURE 64-4** Two keloids in the presternal region, a typical location.

there is increased cellularity and an edematous, myxoid stroma that is replaced by mature collagen over time. Blood vessels are also prominent in early scar formation. With keloids, the collagen is arranged haphazardly, with the presence of large, eosinophilic, keloidal collagen bundles. The early histologic picture of hypertrophic scars resembles that of keloids, but the thickened collagen bundles flatten with time and become oriented parallel to the long axis of the scar.

Hypertrophic scars and keloids remain extremely challenging, particularly in their variable response to treatment. Hypertrophic scars tend to be more responsive than keloids and generally flatten with time. Injection of hypertrophic scars and keloids with intralesional steroids remains a mainstay of therapy, but multiple injections and higher concentrations of triamcinolone (10 to 40 mg/cc) are often required. Often, cryotherapy will be used first to aid in the ease of the injection. This combination has proved beneficial in scar reduction over time.[57] Intralesional steroids, when injected too deeply or aggressively, can cause atrophy. Other injectable treatments that have been proved to have varying success include bleomycin, 5-fluorouracil, tacrolimus, and interferon.[45,48,58]

Surgical excision of larger keloids will often result in recurrent and sometimes even larger keloids. Skin grafting, pressure garments to both the surgical site and the grafted site, and steroid or interferon-α injections to the excision site have been shown to reduce pro-α_1 type I collagen gene expression, hence reducing keloid formation.[59] Other therapies, such as topical retinoids, laser therapy, self-adherent soft silicone dressings, and radiation, have demonstrated varying success rates.[60–63] Intralesional collagenase has recently been proved ineffective.[64]

Nodular Fasciitis

Nodular fasciitis is a benign, self-limiting proliferation of fibroblasts of uncertain etiology that often follows trauma. Although it is seen most commonly in young adults, it can occur at any age, without racial or sex predilection. It presents as a rapidly growing, painful mass in the subcutis, fascia, or muscle. It is observed most frequently on the upper extremity (48 percent), followed by the trunk, head and neck, and lower extremity, in descending order.[65] Cranial fasciitis is the most common variant in children and involves the head and neck.

Histologically, nodular fasciitis presents as a poorly demarcated nodule in the subcutis, fascia, or dermis that is composed of spindled fibroblasts and myofibroblasts and ganglion cell-like fibroblasts in a loose, myxoid, highly vascular stroma that resembles granulation tissue. These lesions often have associated hemorrhage and infiltration of plasma cells, mast cells, and lymphocytes. Mitotic figures are present, but atypia and nuclear polymorphism are not seen. Immunohistochemically, this process stains positive with smooth muscle and muscle-specific actins, vimentin, and CD68. Staining shows no cytokeratin, S100 protein, or desmin.[66]

Despite the possibility of spontaneous involution, excision is the treatment of choice, with recurrences being rare. Due to the fact that this lesion mimics sarcoma clinically, biopsy and excision are necessary to eliminate sarcoma from clinical and radiologic consideration.

Elastofibroma Dorsi

Elastofibroma dorsi is a rarely diagnosed, benign, fibroproliferative, soft-tissue tumor that occurs most commonly in the periscapular region of middle-aged to elderly women. It has a male-female ratio of 1:5. Approximately 10 percent are bilateral. Besides the scapular region, other common locations include the head, as well as the abdominal and thoracic cavities. Although the exact etiology is unknown, it is suspected that chronic subclinical microtrauma may lead to reactive hyperplasia of elastic fibers, with consequently increased production of fibrous tissue. Clinically, this tumor presents as a poorly circumscribed, firm, mobile mass. More than 50 percent of patients are asymptomatic and present with a painless swelling. Magnetic resonance imaging is the best non-invasive technique to visualize the tumor.[69]

Degenerative Collagenous Plaques of the Hands (Keratoelastoidosis Marginalis, Digital Papular Calcific Elastosis)

Degenerative collagenous plaques of the hands present with keratotic, translucent papules in a linear array on the medial and lateral aspects of the fingers and thumbs. Ultraviolet light and chronic pressure or mechanical trauma seem to be the inciting factors.[71] Histologically, the epidermis is hyperkeratotic, and the reticular dermis has a band-like deposition of dense collagen. Solar elastosis is present along with calcified angular elastotic masses termed *basophilic elastotic masses*. Solar elastosis in the absence of this condition lacks basophilic elastotic masses.[71]

Pachydermoperiostosis (Primary Hypertrophic Osteoarthropathy)

Pachydermoperiostosis (primary hypertrophic osteoarthropathy) is a rare syndrome characterized by progressive enlargement of the joints due to pachydermia, periostosis, and clubbing, related to altered proteoglycan synthesis.[72] Other features include coarse facial features, palmoplantar hyperhidrosis, periostosis (fibrous covering at the ends of long bones), and acro-osteolysis. It is a self-limiting disease, but the arthralgias can be quite debilitating. Most recently, there are reports of resolution of the arthralgias when treated with tamoxifen.[73]

Acrokeratoelastoidosis of Costa

Acrochordon (Fibroepithelial Polyp, Skin Tag, Soft Fibroma)

Acrochordons are pedunculated papules or nodules that are most commonly located on the eyelids, neck, and axillae (Fig. 64-5). Larger lesions in the groin or upper thighs may be associated with diabetes mellitus. There is a familial disposition, and acrochordons are more commonly seen in obese individuals. Acrochordons are also a clinical feature of Birt-Hogg-Dubé syndrome, along with fibrofolliculomas and trichodiscomas.[76] Although usually asymptomatic, patients are often cosmetically bothered by these lesions. Furthermore, when the stalk of these pedunculated papules get strangu-

▲ **FIGURE 64-5** Soft fibromas or skin tags on the neck of a female patient who also had (endocrine) acanthosis nigricans.

lated or twisted, the lesions can undergo infarction and become irritated.

Fibrous papule of the nose is a common, solitary papule on the lower portion of the nose. It is small (2 to 5 mm), non-tender, flesh colored (sometimes pink or slightly hyperpigmented), firm, and dome shaped. It must be differentiated from an early, nodular, basal cell carcinoma and is often biopsied for that reason. Unlike a basal cell carcinoma, it rarely bleeds and stays relatively stable in its smaller size. Histologically, the dermis shows a localized area of fibrosis and vascular proliferation. There are large, triangular, and stellate cells. No treatment is necessary, but a simple shave or punch excision is usually curative.

HAMARTOMAS

Fibrous Hamartoma of Infancy

Fibrous hamartoma of infancy is a rare benign tumor that presents as a solitary, painless, rapidly growing, flesh-colored, ill-defined, subcutaneous nodule or plaque. Multiple lesions are rarely reported.[79] Approximately one-fourth are congenital, and 91 percent present during the first year of life. An approximate 2:1 male-female ratio exists. The most common locations are the axillary region, upper arm, upper trunk, inguinal region, and external genital region.[80] These lesions occasionally present with overlying skin changes such as hypertrichosis, alteration in pigmentation, and eccrine gland hyperplasia.[79,80] Some may have an overlying pink hue.

The treatment of choice is complete excision, if feasible. Simple complete excision, as opposed to radical excision, is curative. An aggressive approach should be avoided because the overall prognosis is excellent.[82]

Connective Tissue Nevus/Collagenoma

Connective tissue nevi present as asymptomatic, flesh-colored to yellow-brown papules or plaques that may be solitary or grouped, linear, or irregular in distribution (Fig. 64-6). The overlying epidermis is usually smooth.[83] These hamartomas can be divided into familial, those associated with tuberous sclerosis, eruptive, and other isolated variants. Histologically, connective tissue nevi appear with a normal epidermis overlying increased deposition of dense collagenous bundles in the lower dermis.

▲ **FIGURE 64-6** Cutaneous collagenoma, a connective tissue nevus involving almost the entire back.

Familial cutaneous collagenoma, first described by Henderson et al. in 1968,[84] is an autosomal, dominantly inherited condition of multiple connective tissue nevi usually appearing postpuberty.[85] There may be associated cardiac abnormalities such as progressive cardiomyopathy and conduction defects.[86] Familial collagenomas have a predilection for the trunk and upper extremities. Certain collagenomas may be associated with Gardner syndrome or FAP syndrome (APC gene, 5q21), and clinical, radiologic, and genetic evaluations should be conducted as appropriate.[6,7]

Smooth Muscle Hamartoma (See Chap. 127)

Basaloid Follicular Hamartoma

Angiofibroma

Angiofibromas are small, flesh-colored to brownish-red shiny papules usually distributed on the central face. Multiple facial angiofibromas are a pathognomonic feature of tuberous sclerosis (see Chap. 141).[94]

Pearly penile papules are 1- to 3-mm, pink to flesh-colored papules around the penile coronal sulcus, often in a linear distribution. They are histologically identical to other angiofibromas (see Chap. 75).[95]

Fibrofolliculoma

Fibrofolliculomas are 2- to 4-mm, dome-shaped, yellowish to skin-colored papules located on the head, neck, and upper trunk.[96] Birt-Hogg-Dubé syndrome is an autosomal dominant condition caused by a mutation in the protein folliculin and is comprised of patients with fibrofolliculomas, trichodiscomas, and acrochordons. This condition has an increased risk of renal carcinoma and pneumothoraces (see Chap. 119).[97]

Sclerotic Fibroma (Circumscribed Storiform Collagenoma, Plywood Fibroma)

Giant Cell Collagenoma

Pleomorphic Fibroma

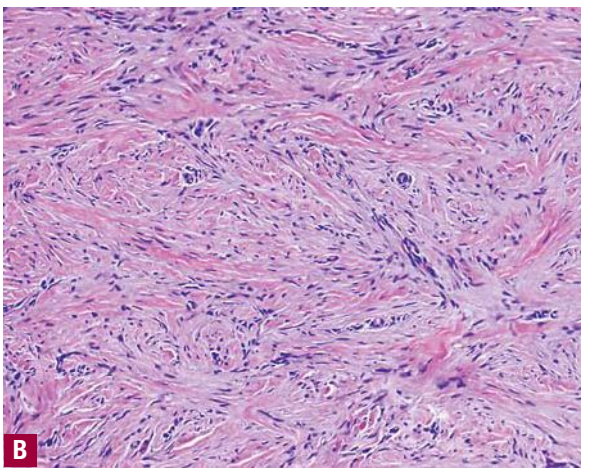
Pleomorphic fibroma is a rare fibrous tumor characterized by nuclear atypia, yet with a benign clinical behavior. This lesion presents as a slow-growing, dome-shaped, or polypoid lesion that may resemble fibrokeratomas, nevi, neurofibromas, or fibroepithelial polyps. Pleomorphic fibromas are usually solitary and appear in middle-aged to older individuals.[102]

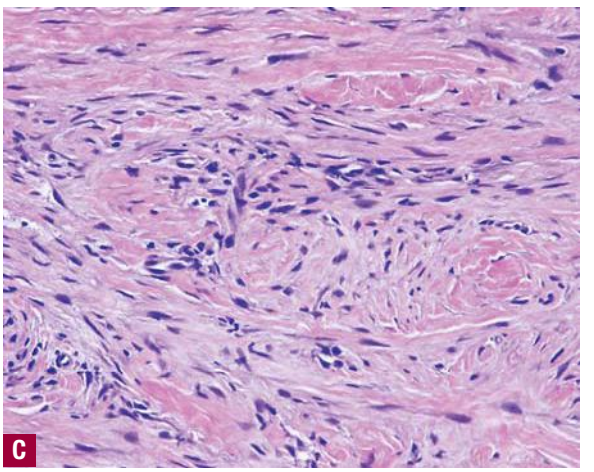
Desmoplastic Fibroblastoma (Collagenous Fibroma)

Desmoplastic fibroblastoma is a benign fibrous tumor that appears as a slow-growing, painless, mobile mass located in the subcutaneous tissue or just deep to skeletal muscle, often with fascial and muscle involvement. This tumor has a predilection for the arm, shoulder, posterior neck, upper back, abdominal wall, and hip joint. It usually presents in the fifth to sixth decades with a 5:1 male-female ratio.[104]

Solitary Fibrous Tumor

Solitary fibrous tumor is a tumor once thought to only involve the pleural cavity, but it is now known to be a rare soft-tissue tumor with a predilection to the head and neck region, although it may involve any anatomic site. It usually behaves as a benign tumor, although more





◀ **FIGURE 64-7** **A.** Dermatofibroma on the right thigh of a young man. **B and C.** Dermatofibromas may be characterized as typical, cellular, and atypical cellular. The typical dermatofibroma is composed of spindle cells in the dermis that are haphazardly arranged into fascicles and lack atypical cytologic features. The lesion edge is poorly defined, and the spindle cells often infiltrate between thickened collagen fibers (hematoxylin and eosin 100× magnification A; 200× magnification B).

aggressive variants and metastatic tumors have been reported.[105]

Dermatofibroma (Cutaneous Benign Fibrous Histiocytoma, Sclerosing Hemangioma)

Dermatofibroma is perhaps the most common mesenchymal growth of the skin. It has a predilection for the lower legs of women in their early 20s. Any age may be affected, but typically dermatofibromas appear in the 20s and 30s. Dermatofibroma is more common in women than in men. The surface may be shiny or keratotic, and the color is usually brown, sometimes with a play of colors ranging from pink to red to tan to flesh-colored (Fig. 64-7A). Characteristically, a dermatofibroma is firm, indurated, and mobile and measures from 0.5 mm to 1 cm in diameter. Lateral compression produces a dimple-like depression in the overlying skin ("buttonholing"). Dermatofibromas may be solitary or multiple, and generalized lesions have been described, as have occasional unusual tumors confined to the palms and soles. Usually asymptomatic, they occasionally are pruritic and may ulcerate after trauma. Some tumors grow very rapidly, whereas others remain static for many years. Regression may leave hypopigmentation. Dermatofibromas arising on the face are uncommon but require special mention. They are more often of cellular type, extend into the subcutaneous fat or muscle, and frequently recur; therefore, a wider initial excision is recommended.[107]

A deeper variant of dermatofibroma can be confused clinically with dermatofibrosarcoma protuberans (see Chap. 125). This dermatofibroma typically is on the trunk and extremities of younger adult patients, extending into the subcutaneous tissue, and tends to be larger in size—1 to 2 cm.

Trauma, such as insect bites, has been thought to induce some lesions. For this reason, some authors classify these as reactive/reparative lesions rather than as neoplasms. However, the recent demonstration of chromosome abnormalities in at least some cases of dermatofibroma supports a neoplastic nature.[108] Of note, the karyotypic changes identified are different from those in dermatofibrosarcoma. A viral etiology also has been considered.

Histologically, the epidermis is usually hyperplastic and hyperpigmented ("dirty fingernail" sign). The dermis has haphazardly arranged fascicles of plump spindle cells that lack atypia in most cases (see Fig. 64-7B, C). The edges of the lesion are poorly defined, with individual cells infiltrating between collagen bundles that are often thickened and hyalinized ("keloidal"). Mitotic figures may be present, but atypical forms are not a feature.

A cellular variant characterized by increased cellularity, storiform arrangement, larger size, and location in the deep dermis, often with extension into the superficial subcutaneous tissue, may be difficult to differentiate from dermatofibrosarcoma protuberans. In such circumstances, immunohistochemical expression of factor XIIIa and fascin (dendritic cell markers) rather than CD34 is often helpful.

A rare group of atypical fibrous histiocytomas[114] is characterized by pleomorphic, plump, spindle, or polyhedral cells with large, hyperchromatic, irregular, or bizarre nuclei set in a background of classic features of fibrous histiocytoma, including a storiform pattern and keloidal collagen. Some lesions attain a diameter of more than 2 cm, invade the superficial subcutis, or exhibit necrosis. Atypical mitotic figures have been noted, as have local recurrence and distant metastases. Thus, lesions with such atypical features must be excised completely and the patients followed up carefully.

Immunolabeling for factor XIIIa and fascin is usually positive in dermatofibroma,[116] but not in dermatofibrosarcoma protuberans.[117] In addition, the more cellular forms of dermatofibroma tend to express α-smooth muscle actin, whereas the lesions with more epithelioid cells and giant cells tend to express histiocytic markers.[118]

No treatment is necessary unless symptomatic. A common reason for surgical removal is due to repeated trauma to the dermatofibroma from shaving the lower legs. Because about 20 percent of cellular dermatofibromas recur after simple biopsy, a fusiform excision into the superficial subcutaneous tissue is recommended. Cryosurgery may be helpful to flatten out the dermatofibroma but usually is not curative. Excision to the deeper subcutaneous tissue is necessary to decrease the risk for recurrence of the deeper variant of dermatofibroma. Two cellular dermatofibromas have metastasized to lymph nodes and lungs.[119] Notably, both original lesions were 2 cm in diameter, an unusually large size for dermatofibroma, and had recurred locally before metastasis.

CHAPTER 65

Anetoderma and Other Atrophic Disorders of the Skin

Catherine Maari
Julie Powell

ANETODERMA

History

Epidemiology

The lesions in anetoderma usually occur in young adults between the age of 15 and 30 years of age and more frequently in women than men. Anetoderma is rare, but the incidence is unknown. Anetoderma has been reported in several hundred cases since the original report.

Pathogenesis

The pathogenesis of anetoderma is unknown. The key defect is damage to the dermal elastic fibers. Anetoderma might be considered to be unusual scars, because scars also have decreased elastic tissue. The loss of dermal elastin could be the result of an impaired turnover of elastin caused by either increased destruction or decreased synthesis of elastic fibers.

Clinical Findings

All types of anetoderma are characterized by a circumscribed loss of normal skin elasticity. The characteristic lesions are flaccid circumscribed areas of slack skin with the impression of loss of dermal substance forming depressions, wrinkling, or sac-like protrusions (Fig. 65-1). These atrophic, skin-colored, or blue-white lesions are 5 to 30 mm in diameter. The number varies from a few to hundreds. The skin surface can be wrinkled, thinned, and often depigmented, and a central depression may be seen. Coalescence of smaller lesions can give rise to larger herniations. The examining finger sinks without resistance into a distinct pit with sharp borders as if into a hernia ring (buttonhole sign). The protrusion reappears as soon as the pressure from the finger is removed.[4]

The most common sites for these asymptomatic lesions are the chest, back, neck, and upper extremities. They usually develop in young adults, and new lesions often continue to form for many years as the older lesions fail to resolve.

Primary anetoderma occurs when there is no underlying associated skin disease (i.e., it arises on clinically normal skin). It is historically subdivided into two types: (1) those with preceding inflammatory lesions, mainly erythema (the Jadassohn-Pellizzari type), and (2) those without preceding inflammatory lesions (the Schweninger-Buzzi type). This classification is only of historical interest, because the two types of lesions can co-exist in the same patient; the prognosis and the histopathology are also the same.[4]

True secondary anetoderma implies that the characteristic atrophic lesion has appeared in the exact same site as a previous specific pathology; the most common causes are probably acne and varicella. Numerous and heterogeneous dermatoses have been associated with secondary anetoderma, namely syphilis, Lyme disease, molluscum contagiosum, pilomatricomas, juvenile xanthogranuloma, xanthomas, granuloma annulare, leprosy, discoid lupus, sarcoidosis, and lichen planus, to mention only a few. Anetoderma has also been described in premature infants and, in some cases, it

ANETODERMA AT A GLANCE

- Circumscribed 1- to 2-cm areas of flaccid skin that may be elevated, macular, or depressed.
- Often circumscribed sac-like protrusions.
- Primary or secondary to a preceding dermatosis in the same location.
- Pathology consists of loss of elastic tissue in the dermis.

▲ **FIGURE 65-1** Anetoderma. Primary anetoderma. **A.** Multiple, sharply defined, depressed lesions that look punched out in the supraclavicular region. **B.** Soft, sac-like protrusions on the back. When depressed, there is the buttonhole phenomenon. This is the same patient as in **A**.

may have been related to the use of cutaneous monitoring leads or adhesives.[5] Both types may be associated with an underlying disease, mainly anti-phospholipid syndrome and human immunodeficiency virus. Although most cases are sporadic, rare cases of familial anetoderma have been recently described and are usually not associated with preexisting lesions.[6]

Pathology

In routinely stained sections, the collagen fibers within the dermis of affected skin appear normal. Perivascular lymphocytes are often present in all types of anetoderma and do not correlate with clinical inflammatory findings.[7]

The predominant defect as revealed by elastic tissue stains is a focal partial or complete loss of elastic tissue in the papillary and/or mid-reticular dermis. There are usually some residual abnormal, irregular, and fragmented elastic fibers (Fig. 65-2).[8] Presumably, the weakening of the elastic network leads to flaccidity and herniation. Direct immunofluorescence sometimes shows linear or granular deposits of immunoglobulins and complement along the dermal-epidermal junction or around the dermal blood vessels in affected skin.[9] Electron microscopy demonstrates that the elastic fibers are fragmented and irregular in appearance and occasionally can be engulfed by macrophages.

Differential Diagnosis

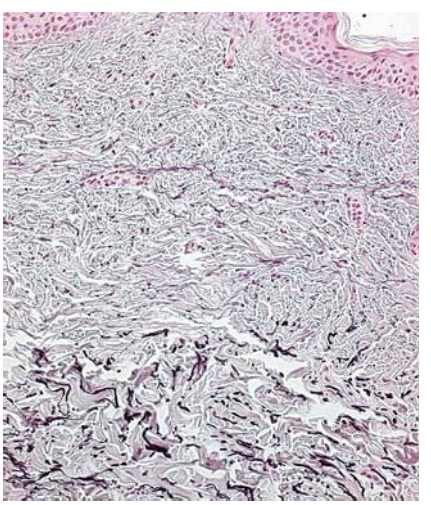
Anetoderma must be differentiated from other disorders of elastic tissue as well as atrophies of the connective tissue.

Keloids form nodules that are much firmer on palpation. A history of trauma is often elicited, and the pathology is very distinct.

Glucocorticoid-induced atrophy occurs most commonly over the triceps or buttocks at sites where injections are usually given. Clinically, the lesions resemble atrophoderma. History is obviously most helpful in making the diagnosis. Polarization may show the steroid crystals in the dermis.

Nevus lipomatosus superficialis of Hoffman and Zurhelle presents as a clustered group of soft, skin-colored to yellow nodules usually on the lower trunk and buttocks and present since birth. Histology shows ectopic mature lipocytes located in the dermis.

Papular elastorrhexis is an acquired disorder characterized by white, firm non-follicular papules measuring 1 to 3 mm, evenly scattered on the chest, abdomen, and back. It usually appears in adolescence or early adulthood. The pathology demonstrates focal degeneration of elastic fibers and normal collagen. There are no associated extra-cutaneous abnormalities. This is believed by some authors to be a variant of connective tissue nevi[10] or an abortive form of the Buschke-Ollendorff syndrome,[11] whereas others think that these represent papular acne scars.[12] They are differentiated from anetoderma by being firm non-compressible lesions.



▲ **FIGURE 65-2** Anetoderma. Pathology shows decrease of elastic fibers in the papillary and reticular dermis (Weigert's stain). (Used with permission from Victor Kokta, MD.)

Box 65-1

Nevus lipomatosus superficialis	
Papular elastorrhexis	
Connective tissue nevi	

Mid-dermal elastolysis (MDE) usually consists of larger areas with diffuse wrinkling without herniation and with elastolysis limited to the mid-dermis (Box 65-1).

Treatment

There is no regularly effective treatment. In secondary anetoderma, appropriate treatment of the inflammatory underlying condition might prevent new lesions. In patients with limited lesions that are cosmetically objectionable, surgical excision may be useful. Various therapeutic modalities have been tried but with no improvement of existing atrophic lesions, including intralesional injections of triamcinolone and systemic administration of aspirin, dapsone, phenytoin, penicillin G (benzylpenicillin), and vitamin E. Some authors have reported improvement with hydroxychloroquine.

OTHER ATROPHIC DISORDERS OF THE SKIN

Mid-Dermal Elastolysis

MDE is a rare acquired disorder of elastic tissue. It is characterized by patches and plaques of diffuse, fine, wrinkled skin, most often located on the trunk, neck, and arms. In 1977, Shelley and Wood reported the first case of "wrinkles due to idiopathic loss of mid-dermal elastic tis-

sue."[13] Since then, fewer than 100 cases have been reported. The vast majority of patients are Caucasian women between the ages of 30 and 50 years.[14]

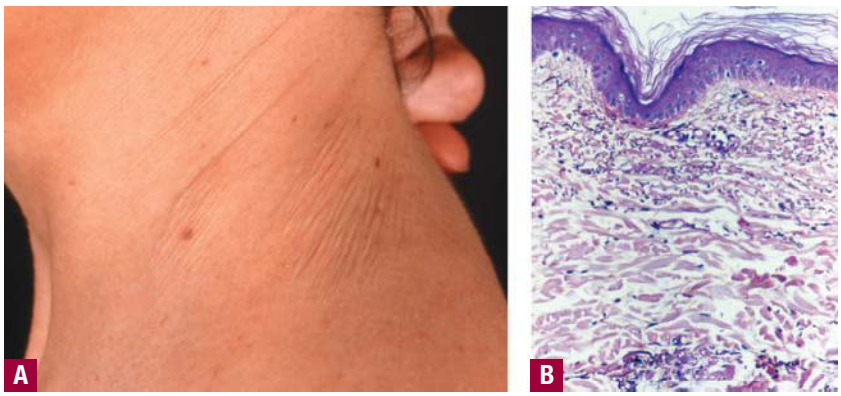
PATHOGENESIS The pathogenesis of this acquired elastic tissue degeneration is still unclear. Ultraviolet exposure has been postulated to be a major contributing factor in the degeneration of elastic fibers.[15] Other possible mechanisms include defects in the synthesis of elastic fibers, autoimmunity against elastic fibers, and damage to elastic fibers through the release of elastase by inflammatory cells or fibroblasts. More recent data suggest that inflammatory processes and an altered balance between matrix metalloproteinase and tissue inhibitor of metalloproteinases are possibly involved in the pathogenesis of MDE.[16]

CLINICAL FEATURES MDE is characterized by asymptomatic, well-demarcated, or diffuse areas of fine wrinkling (Fig. 65-3A). Rarely, erythematous patches and telangiectasias can be seen. Discrete perifollicular papules can be seen in some cases, leaving the hair follicle itself as an indented center. Lesions are typically found on the trunk, neck, and upper extremities. They are chronic and give the skin a prematurely aged appearance. There is usually no history of a preceding inflammatory dermatosis, but some patients report mild to moderate erythema. There is no associated systemic involvement.

HISTOPATHOLOGY The pathology shows a normal epidermis and, occasionally, a mild perivascular infiltrate in the dermis. The characteristic histology is seen on elastic tissue stains and reveals a selective band-like loss of elastic fibers in the mid-dermis (see Fig. 65-3B). There is preservation of normal elastic tissue in the superficial papillary dermis above, in the reticular dermis below, and along adjacent hair follicles. Electron microscopy studies have shown phagocytosis of normal as well as degenerated elastic fiber tissue by macrophages.[17]

DIFFERENTIAL DIAGNOSIS MDE must be differentiated from the other common disorders of elastic tissue.

Solar elastosis differs by its onset in an older age group, location in only sun-exposed areas, yellowish color, and coarser wrinkling, as well as by hyperplasia and abnormalities of elastic fibers and basophilic degeneration of the collagen in the papillary dermis.



▲ **FIGURE 65-3** Mid-dermal elastolysis. **A.** Well-circumscribed area of fine wrinkling on the neck of a middle-aged woman. (Used with permission from Richard Dubuc, MD.) **B.** Histology of mid-dermal elastolysis. Note selective loss of elastic fibers in the mid-dermis. Normal elastic tissue is preserved in the superficial papillary dermis and in the reticular dermis (Weigert's stain). (Used with permission from Danielle Bouffard, MD.)

Anetoderma is characterized clinically by smaller soft macules and papules instead of diffuse wrinkling, and histologically by elastolysis that can occur in any layer of the dermis.

Perifollicular elastolysis differs by a selective and almost complete loss of elastic fibers surrounding hair follicles compared with preservation of elastic fibers around follicles in MDE. Elastase-producing *Staphylococcus epidermidis* was found in the hair follicles and is the presumed etiology of this condition.[18]

Post-inflammatory elastolysis and cutis laxa were originally described in young girls of African descent. An inflammatory phase, consisting of indurated plaques or urticaria, malaise, and fever, preceded the diffuse wrinkling, atrophy, and severe disfigurement. Insect bites may be the trigger for the initial inflammatory lesions.[19]

TREATMENT There is no known effective treatment for MDE. Sunscreens, colchicine, and topical retinoic acid have been tried without good success.[14]

Striae (See Chaps. 107 and 152)

Striae are very common and usually develop between the ages of 5 and 50 years.

They occur about twice as frequently in women as in men. They commonly develop during puberty, with an overall incidence of 25 percent to 35 percent,[20,21] or during pregnancy, with an incidence of 77 percent.[22]

The factors leading to the development of striae have not been fully elucidated. Striae distensae are the results of breaks in the connective tissue, resulting in dermal atrophy. Many factors, including hormones (particularly corticosteroids), mechanical stress, and genetic predisposition, appear to play a role.

During puberty, striae appear in areas where there is a rapid increase in size. In girls, the most common sites are the breasts, thighs, hips, and buttocks, whereas in boys, they are seen on the shoulders, lumbosacral region, and thighs. Other less common sites include the abdomen, upper arms, neck, and axillae.

Striae distensae are a common finding on the abdomen, and less so the breasts and thighs, of pregnant women, especially during the last trimester. They are more common in younger primigravidas than in older pregnant women. Striae gravidarum can be associated with a higher risk of lacerations during vaginal delivery.[23]

CLINICAL FINDINGS Striae are usually multiple, symmetric, well-defined linear atrophic lesions that follow the lines of cleavage. Initially, striae appear as red-to-violaceous elevated lines (striae rubra) (see Fig. 107-3). Over time, the color gradually fades, and the lesions become atrophic, with the skin surface exhibiting a fine, white, wrinkled appearance (striae alba).[21] The striae can measure several centimeters in length and a few millimeters to a few centimeters in width. The striae associated with systemic corticosteroid therapy and Cushing syndrome can be larger and more widely distributed.

HISTOPATHOLOGY Histologic findings show a decrease in dermal thickness and in collagen in the upper dermis. The collagen bundles are thinned and lie parallel to the epidermis, but they are also arranged transversely to the direction of the striae. Alterations in elastic fibers are variable, but dermal elastin can be fragmented, and specific elastin staining can

demonstrate a marked reduction in visible elastin content compared with adjacent normal dermis.[24] There is absence of both hair follicles and other appendages.

DIFFERENTIAL DIAGNOSIS The diagnosis of striae distensae is usually simple, but the differential diagnosis does include linear focal elastosis (elastotic striae) that was first described by Burket et al. in 1989.[25] Linear focal elastosis is characterized by rows of yellow palpable striae-like bands on the lower back. Unlike striae, the lesions are raised and yellow rather than depressed and white. Elderly men are most commonly affected, although cases in teenagers have been described. Linear focal elastosis is probably not an uncommon condition. Histologically, there is a focal increase in the number of elongated or fragmented elastic fibers and a thickened dermis. It is postulated that linear focal elastosis may represent an excessive regenerative process of elastic fibers and could be thought of as a keloidal repair of striae distensae.[26]

TREATMENT Striae distensae have no medical consequences, but they are frequently distressing to those affected. As stretch marks tend to regress spontaneously to some degree over time, the usefulness of treatments that have been tried without case controls is difficult to assess. Topical treatments that have shown some improvement of early stage striae are: tretinoin 0.1 percent cream,[27] a combination of 0.05 percent tretinoin/20 percent glycolic acid, or 10 percent L-ascorbic acid/20 percent glycolic acid.[28] Several lasers have been used in treating striae: the 585-nm pulsed-dye laser has been demonstrated to be of some efficacy in improving the appearance of striae rubra but has no effect on stria alba[29]; improvement in the leukoderma of the striae alba was noted with 308-nm excimer laser but maintenance treatment is required to sustain the cosmetic benefit.[30]

Idiopathic Atrophoderma of Pasini and Pierini

EPIDEMIOLOGY AND PATHOGENESIS Idiopathic atrophoderma of Pasini and Pierini is a form of dermal atrophy that presents as one or several sharply demarcated depressed patches with no outpouching, usually on the back of adolescents or young adults.[31] Whether atrophoderma is a nonsclerotic, primarily atrophic variant of morphea or a separate distinct entity is still debated.[32–35] Its relationship to morphea is favored by its striking clinical and histologic similarities to the atrophy seen at sites of regressing plaques of morphea. Antibodies to *Borrelia burgdorferi* have been reported.[33] Typical lesions of morphea, lichen sclerosus, and atrophoderma have been observed to occur simultaneously in the same patient but in different areas, supporting the view that these conditions are related. In a series of 139 patients, 17 percent had white induration in the central portions of their atrophic lesions, and 22 percent had superficial plaques of morphea co-existing in areas outside of their atrophic foci.[32] However, to some, the different course and outcome of atrophoderma of Pierini and Pasini as compared with morphea justifies preservation of a distinct name.

This disorder is more frequently encountered in women than in men, with a ratio of 6:1. It usually starts insidiously in young individuals in the second or third decades of life. The lesions usually occur on the trunk, especially on the back and lumbosacral region, followed in frequency by the chest, arms, and abdomen.[33] The distribution is often symmetric and bilateral.

The lesions are single or multiple and usually round or ovoid, ranging in size from a few centimeters to patches covering large areas of the trunk (Fig. 65-4). They are usually asymptomatic and lack inflammation. When lesions coalesce, they can form large, irregular, brown patches. The surface of the skin is normal in appearance, and there is no skin induration or sclerosis.

The borders or edges of these lesions are sharply defined, and they are usually described as abrupt, "cliff drop" borders ranging from 1 to 8 mm in depth, although they can have a gradual slant.[31] These depressed patches are characteristic and give the impression of inverted plateaus, or, if multiple lesions are present, they can have the appearance of Swiss cheese. They are even more apparent when present on the back because the dermis is thicker in this area. The skin surrounding the patches is normal in appearance, and there is no erythema or lilac ring as in morphea.

▲ **FIGURE 65-4** Atrophoderma of Pasini and Pierini. Brownish depressed lesions on the lower back.

COURSE The course of this benign disease is progressive, and lesions can continue to appear for decades before reaching a standstill. Transformation to generalized morphea has not been observed.

HISTOPATHOLOGY The histologic picture is generally not diagnostic. The epidermis is usually normal or slightly atrophic. Collagen bundles in the mid- and reticular dermis show varying degrees of homogenization and clumping. Dermal thickness is eventually reduced when compared with adjacent normal skin.[34] Some irregular clumping and loss of elastic fibers were described in earlier case reports,[31] but in most series, no abnormality was seen with elastic tissue stains[32,33]; therefore, this is not of diagnostic value. The appendages are usually preserved. If sclerodermatous changes appear in pre-existing patches, the histology reveals varying degrees of collagen sclerosis resembling morphea.

DIFFERENTIAL DIAGNOSIS The differential diagnosis is to be made with active lesions of morphea that usually present as indurated, often hyperpigmented plaques with a characteristic peripheral lilac rim.

THERAPY No treatment has been proved effective.

Follicular Atrophoderma

Follicular atrophoderma refers to dimple-like depressions at the follicular orifices. It can occur as an isolated defect of limited extent, in association with a variety of disorders in which hair follicles are plugged with keratin, or with rare genodermatoses.[36,37]

Distinctive ice-pick depressions around hair follicles can be seen most commonly on the back of the hands or feet and on the cheeks. These pitted scars can present at birth or early in life. A family history may be present. Follicular atrophoderma occurs in the conditions described in the following sections.

ATROPHODERMA VERMICULATUM *Atrophoderma vermiculatum* is a term that applies when the lesions are found exclusively on the cheeks. It is a condition that can

▲ **FIGURE 65-5** Atrophoderma vermiculatum. Multiple, small, pitted scars on the cheek of a young girl.

▲ **FIGURE 65-6** Ulerythema ophryogenes. Erythematous follicular papules and scarring alopecia of the eyebrow.

either occur sporadically, be inherited as an autosomal dominant disorder, be part of a group of related diseases including keratosis pilaris atrophicans, or be associated with various syndromes.

Multiple inflammatory symmetric papules on the cheeks, presumably centered around hair follicles, may precede the atrophic lesions. These papules then go on to develop pitted, atrophic, and depressed scars in a reticulated or honeycomb pattern (Fig. 65-5). These lesions can extend to the forehead and preauricular regions. This condition usually has its onset in childhood or, less often, around puberty. Men and women seem to be affected equally.[38] It usually has a slow progressive course.

Keratosis Pilaris Atrophicans. Keratosis pilaris atrophicans[39] can include atrophoderma vermiculatum but also a group of closely related disorders that includes keratosis follicularis spinulosa decalvans and ulerythema ophryogenes. These conditions are characterized by keratotic follicular papules, variable degrees of inflammation, and secondary atrophic scarring. Keratosis follicularis spinulosa decalvans begins in infancy with keratotic follicular papules over the malar area and progresses to involve the eyebrows, scalp, and extremities, with scarring alopecia. This condition is inherited in an X-linked recessive fashion in some patients. Ulerythema ophryogenes (or keratosis pilaris atrophicans faciei) differs from atrophoderma vermiculatum by affecting primarily the lateral portion of the eyebrows (ophryogenes) with erythema, follicular papules, and alopecia (Fig. 65-6).

The underlying pathologic defect in these disorders appears to be abnormal follicular hyperkeratinization of the upper third of the hair shaft leading to obstruction of the growing hair and production of chronic inflammation. The end result of this process is scarring below that level. Histopathology is usually not very helpful and shows dilated follicles, sometimes associated with plugging, inflammation, and sclerosis of dermal collagen.

Associated Syndromes. The various syndromes that include atrophoderma vermiculatum are the Rombo syndrome (milia, telangiectasias, basal cell carcinomas, hypotrichosis, acral cyanosis, and, rarely, trichoepitheliomas), Nicolau-Balus syndrome (syringomas and milia), Tuzun syndrome (scrotal tongue), and finally the Braun-Falco-Marghescu syndrome (palmoplantar hyperkeratosis and keratosis pilaris).

Therapy. These disorders are mainly a cosmetic but vexing problem. Various topical treatments, including emollients, corticosteroids, tretinoin, and keratolytics, have shown no consistent benefit. Systemic isotretinoin has been shown to stop progression and to induce remission in some cases.[39] Dermabrasion as well as carbon dioxide and 585-nm pulsed-dye lasers are other options to improve the appearance of the atrophic scars.[40]

BAZEX SYNDROME Bazex syndrome is characterized by follicular atrophoderma, multiple basal cell carcinomas, hypotrichosis, and localized hypohidrosis. The follicular atrophoderma described as multiple ice-pick marks or patulous follicles can be found most commonly on the dorsa of the hands. It is inherited in an X-linked dominant fashion, and the gene has been linked to Xq24–q27.[41] Subsequently reported findings include facial hyperpigmentation, milia, hair shaft dystrophy, and multiple genital trichoepitheliomas.

CONRADI-HÜNERMANN SYNDROME (X-LINKED DOMINANT CHONDRODYSPLASIA PUNCTATA) Conradi-Hünermann syndrome is an X-linked dominant disorder that occurs only in girls because it is usually lethal in hemizygous males. The underlying molecular defect consists of mutations in the emopamil binding protein gene at Xp11.23-p11.22.[42] The clinical manifestations include an ichthyosiform scaling erythroderma patterned along the lines of Blaschko that usually resolves during the first year of life and is replaced by bands of follicular atrophoderma.[43] Hyperpigmentation, cataracts, scarring alopecia, saddle-nose deformity, asymmetric limb reduction defects, and stippled calcifications of the epiphyses can be seen. Ichthyosis with keratotic follicular plugs containing dystrophic calcification in newborns are distinctive histopathologic features.[42]

OTHER ATROPHIES OF THE CONNECTIVE TISSUE

Many systemic conditions [scleroderma (see Chap. 158), lupus erythematosus (see Chap. 156), dermatomyositis (see Chap. 157)], and genodermatoses (poikiloderma congenitale, dyskeratosis congenita, Cockayne syndrome, Hallermann-Streiff syndrome) have skin atrophy as an associated finding and are described in other chapters.

CHAPTER 66

Constricting Bands (Ainhum and Pseudoainhum)

Robert T. Brodell
Stephen E. Helms

AINHUM AND PSEUDOAINHUM

Constricting bands are classified as ainhum and pseudoainhum. Ainhum is the development of constricting bands around toes in underdeveloped countries of Africa and may ultimately result in autoamputation. In the African Yorub language, *ainhum* means "to saw or file," and in the Brazilian patois it means "fissure."[1] In the remainder of the world, constricting bands that mimic ainhum are termed *pseudoainhum*.

EPIDEMIOLOGY

Ainhum (dactylolysis spontanea) is traditionally a disease of middle-aged African males accustomed to going barefoot. In tropic and sub-tropic climates its incidence has been reported as between 0.015 percent and 2.0 percent of the population.[2] This same condition is rarely seen throughout the rest of the world. Occasional isolated cases have been reported in North America.[3] Pseudoainhum of all types is very rare.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of ainhum has not been clearly elucidated. Chronic trauma, infection, hyperkeratosis, decreased vascular supply, and impaired sensation may produce excessive fibroplasia in a susceptible host. Dent et al. described impaired blood supply to the foot proximal to the groove at the plantar digital junction. Poor perfusion was the result of attenuation of the posterior tibial artery and absence of the plantar arterial arch, which led to abnormal healing after mechanical trauma. Ainhum has also been blamed on rotational stress applied to the bare, mechanically unstable foot.[4]

There are three pathophysiologic categories of pseudoainhum: (1) congenital constricting bands caused by the umbilical cord; (2) constriction due to external forces, such as hairs or threads, which are generally factitial; and (3) constricting bands secondary to other diseases. The latter may be hereditary or non-hereditary. Hereditary causes include pachyonychia congenita, mal de Meleda, mutilating keratoderma, and psoriasis. Non-hereditary causes include vascular anomalies as seen in Raynaud disease, diabetes mellitus, linear scleroderma, and systemic sclerosis. Sensory changes associated with leprosy, tertiary syphilis, syringomyelia, and spinal cord tumors as well as trauma resulting in scar formation from burns, frostbite, and physical trauma can also cause constricting bands to form.[5,6] When pseudoainhum is associated with chronic trauma and infection of the extremities, the pathophysiology may be identical to that of true ainhum.

CONSTRICTING BANDS AT A GLANCE

- Constricting bands (ainhum and pseudoainhum) cause amputation (autoamputation) of digits.
- Ainhum is a constricting band around a digit and is most common in the tropics and sub-tropics.
- It is most common around the fifth toe of people walking barefoot.
- Pseudoainhum constrictions mimic ainhum clinically and are more common in the developed world. They are caused by the following:
  - Amniotic bands
  - Constrictions associated with keratotic disorders, infections, and trauma
  - Constriction by external materials such as hairs and threads
- Treatment is removal of the foreign strands or surgical intervention.

CLINICAL FINDINGS

Ainhum usually affects the fifth toe (Fig. 66-1). It may be unilateral, but 75 percent of cases are bilateral. In early lesions, a groove or sulcus appears at the plantar junction of the toe and the sole. As this sulcus deepens, edema develops distally, and roentgenographic examination shows resorption of the underlying bone and ultimately autoamputation.

▲ **FIGURE 66-1** Ainhum in an African male. (Used with permission from Wayne M. Meyers, MD.)

Congenital constricting bands (Streeter's bands) usually involve more than one part of the body (see eFig. 66-1.1 in on-line edition). They frequently encircle large structures such as limbs or even the trunk (Fig. 66-2). They persist throughout life and interfere with normal growth of the involved segment unless surgically treated.[7] In more than 50 percent of cases, they are associated with other congenital anomalies, usually syndactyly or clubfoot when constricting bands are found on the feet.[8]

Artifactual pseudoainhum may prove to be a most challenging diagnosis. Strands of hair, fibers, or threads may be intentionally wrapped around digits or other body parts such as a nipple or pe-

▲ **FIGURE 66-3** Pseudoainhum on the fifth finger of a patient with severe psoriasis. (Used with permission from R. J. Crowley, MD.)

nis. This phenomenon is most commonly encountered in children but can occur in mentally ill adults.[9] Because of soft-tissue swelling, the ligating band may not be visible and the true cause of the condition may not be immediately recognized.[9]

Acquired constricting bands are associated with a variety of medical and dermatologic conditions. In general, pseudoainhum is more likely to involve any of the toes or even the hands. In children, when chronic dermatophyte infection is identified and appropriately treated, complete reversal of the constriction may occur. Severe hyperkeratosis as occurs in Vohwinkel syndrome or keratoderma hereditarium mutilans may show constricting bands due to palmar and plantar hyperkeratoses as well as starfish-like and linear keratoses (see Chap. 48). Pseudoainhum may occur in severe psoriasis of the digits (Fig. 66-3).

The pathology of ainhum and pseudoainhum is similar, with the presence of fibrotic bands resembling scar tissue. The bands in ainhum usually extend deep into the subcutaneous layers and may impinge on underlying skeletal and vascular structures. In addition, moderate inflammation and epidermal or verrucous hyperplasia may be present. In pseudoainhum the bands tend to be more superficial. Also, in pseudoainhum there may be histologic clues to the associated disorder, such as dermatophytosis, foreign bodies, or distinct patterns of keratinization.

COMPLICATIONS

The constricting bands of both ainhum and pseudoainhum ultimately produce a dangling, twisted digit, which can become gangrenous or infected. When this tenuous connection leads to necrosis, autoamputation occurs.

PROGNOSIS AND CLINICAL COURSE

Diseases caused by constricting bands proceed slowly and often painfully over many years, eventuating in autoamputation in severe cases.

TREATMENT

Surgery is the mainstay of therapy, and early intervention is important. In most cases of ainhum, prompt amputation may allow the patient to escape pain and infection. Early cases of ainhum or pseudoainhum may respond to conservative plastic repair with a Z-plasty or similar relaxing closure that prevents further disease progression and damage to underlying structures.[10]

Impending amputation in Vohwinkel syndrome can sometimes be aborted by therapy with oral etretinate (see eFig. 66-3.1 in on-line edition). When chronic fungal or bacterial infections are diagnosed in the early phase of band formation, treatment may reverse the threat to the digit. Other predisposing causes or underlying diseases should be treated aggressively in the hope of forestalling progression.

PREVENTION

Ainhum is rarely seen in people whose feet are protected by wearing shoes. Congenital pseudoainhum cannot be prevented and can lead to serious birth defects (see eFig. 66-3.2 in on-line edition). Psychological counseling may prevent recurrences of pseudoainhum in patients with factitial disease. Control of the underlying disease process may delay progression or prevent recurrence in pseudoainhum of the acquired type.

CHAPTER 67

Acquired Perforating Disorders

Mark Lebwohl

ACQUIRED PERFORATING DISORDERS: AN OVERVIEW

Acquired perforating disorders consist of a group of conditions that share some clinical and histologic features. All are characterized by the transepidermal extrusion of dermal material, which clinically presents as umbilicated skin-colored papules with a central white crust. The term *perforating disorder of renal disease* has been applied to these disorders, with the exception of elastosis perforans serpiginosa (EPS), which is clinically and histologically unique.

Acquired Perforating Dermatosis

Kyrle disease, perforating folliculitis, reactive perforating collagenosis, and acquired perforating dermatosis have been reported independently of one another with differing histologies and, at times, differing clinical associations. The primary lesion in all of these conditions is an umbilicated papule with a central hyperkeratotic crust. All of the conditions have been associated with diabetes or renal failure and with the Koebner phenomenon. All have perforation of the epidermis in common, either by degenerated connective tissue that is eliminated through the epidermis (inside out) or hyperkeratotic material that penetrates into the dermis (outside in). In one study, 6 of 55 chronic dialysis patients had reactive perforating collagenosis.[1] Histologically, perforating collagen bundles are the hallmark of reactive perforating collagenosis, but these have been demonstrated in patients thought to have Kyrle disease or perforating folliculitis as well. Consequently, as long as more is learned about the pathogenesis, some authors prefer to consider them under the term *acquired perforating dermatosis* (Table 67-1).

Acquired perforating dermatosis

HISTORY

ETIOLOGY AND PATHOGENESIS Little has been done to elucidate the mechanism by which perforating disorders occur. However, it is clear that trauma is a major trigger of perforating disorders, although the molecular basis to explain the development of lesions after trauma is unclear.

Many patients exhibit the Koebner phenomenon, and lesions can be produced experimentally by traumatizing the skin[10] and after laser hair removal.[11] Other reported triggers of perforating disorders have been elevated plasma silicon in patients on dialysis,[12] vitamin A deficiency[13,14] or excess,[15] and saltwater chemical burns.[16] Evidence supports an underlying dermal microvasculopathy in some patients[17] and aberrant epidermal migration in others.[18]

Based on light and electron microscopic examination of biopsies, an abnormal healing response after excoriation has been described, in which the regenerating epidermis forms epidermal tunnels through which the central necrotic mass and its associated collagen bundles are lifted.[19] The demonstration of type IV collagen within eliminated material suggests extrusion of basement membrane in this process.[20]

CLINICAL FINDINGS Fig. 67-1 shows the approach to the patient with perforating diseases.

Cutaneous Lesions. The acquired perforating disorders are characterized by umbilicated papules with central white, keratotic crusts (Fig. 67-2). Lesions can become quite hyperkeratotic and can resemble prurigo nodularis (Fig. 67-3). Lesions most often develop on the arms and legs, but any site on the cutaneous surface can be affected, including the trunk and scalp. Lesions have even been described on the conjunctiva and buccal mucosa of a patient with Kyrle disease.[21] Virtually all patients complain of pruritus, and scratching can lead to a Koebner phenomenon with linear umbilicated papules arising in excoriated skin.

Related Physical Findings. In the original description of reactive perforating collagenosis, renal failure and diabetes were not highlighted.[9] Nevertheless, most acquired perforating disorders are seen in association with kidney failure, diabetes, or both. However, Kyrle disease has also been described in young siblings without diabetes or kidney disease.[22] Associations with hyperparathyroidism, hypothyroidism, and liver disorders,[23] as well as human immunodeficiency virus infection,[24] pulmonary fibrosis,[25] Poland syndrome,[26] Hodgkin disease,[27] and primary sclerosing cholangitis,[28,29] have also been reported, but these may be coincidental. There have been several cases of acquired perforating disorder reported in patients with scabies.[30] This association has been attributed to koebnerization associated with scratching.

Histopathology. Histologically, the acquired perforating disorders are character-

ACQUIRED PERFORATING DISORDERS AT A GLANCE

- Acquired perforating disorders consist of a group of rare conditions characterized by transepithelial elimination of dermal material. With the exception of elastosis perforans serpiginosa (EPS), there is considerable overlap among the disorders, leading some authors to call the group *perforating disorders of diabetes and renal disease.*
- Chronic pruritic conditions triggered by trauma.
- Umbilicated papules with central white, keratotic crusts; lesions tend to be serpiginous in EPS.
- EPS is associated with inherited disorders of connective tissue and occurs in patients treated with D-penicillamine; other perforating disorders are associated with diabetes mellitus and renal failure.
- Histologically, the acquired perforating disorders are characterized by invagination of the epidermis with extrusion of dermal material through the cup-shaped epidermal depression. Follicular perforation and presence of collagen bundles or elastic fibers in the perforating material distinguishes perforating folliculitis, reactive perforating collagenosis, and EPS from one another.

	Elastosis perforans serpiginosa	Other acquired perforating diseases
History	D-penicillamine therapy	• diabetes • renal failure • hemodialysis
Physical examination	Serpiginous umbilicated papules, examine for: • Down syndrome • Marfan syndrome • Ehlers-Danlos syndrome • cutis laxa • osteogenesis imperfecta • Rothmund-Thomson syndrome • pseudoxanthoma elasticum	• Koebner phenomenon • umbilicated papules
Lab studies		Chemistry screen with serum glucose, BUN, creatinine
Treatment	First line • topical retinoids • UVB Second line • cryotherapy • laser	If patient has renal disease, stabilization of disease or transplantation may result in improvement of perforating disorders. In the absence of renal disease or if stabilization of renal disease is ineffective, topical retinoids or broadband UVB are first-line therapies. If first-line therapies are ineffective, PUVA, oral retinoids (isotretinoin, acitretin), oral antibiotics (doxycycline, clindamycin), and oral allopurinol have been effective in case reports.

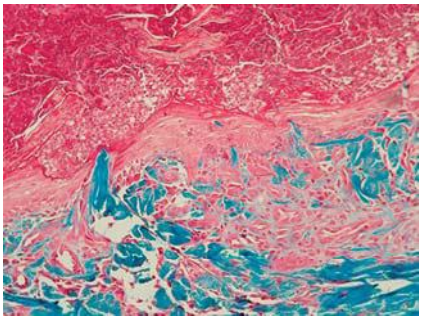
▲ **FIGURE 67-1** Approach to the patient with perforating diseases. BUN = blood urea nitrogen; PUVA = psoralen and ultraviolet A light; UVB = ultraviolet B.

▶ **FIGURE 67-2** Acquired perforating dermatosis. Umbilicated, keratotic papules on the arm of a patient with diabetes and renal failure.

▶ **FIGURE 67-3** Warty and crater-like hyperkeratoses on the foot of a boy with Kyrle disease.

ized by invagination of the epidermis with extrusion of dermal material through the cup-shaped epidermal depression into the necrotic basophilic tissue within the invaginated epidermis. In the past, attempts were made to differentiate among perforating folliculitis, reactive perforating collagenosis, and Kyrle disease based on the nature of the perforating material. In reactive perforating collagenosis, collagen bundles perforate through the epidermis (Fig. 67-4), in contrast to amorphous dermal material and/or keratin that perforates through the epidermis in Kyrle disease. Perforating folliculitis is characterized histologically by follicular perforation.

In perforating folliculitis, there is a focal inflammatory infiltrate adjacent to areas of perforation of the follicular epithelium. Degenerating collagen and extracellular matrix tissues mixed with inflammatory cells and orthokeratotic and parakeratotic material fill the dilated hair follicle. Occasionally, a hair is seen. One author suggested that lesions begin as follicular pustules and develop into perforating folliculitis and, ultimately, into prurigo nodularis.[31]

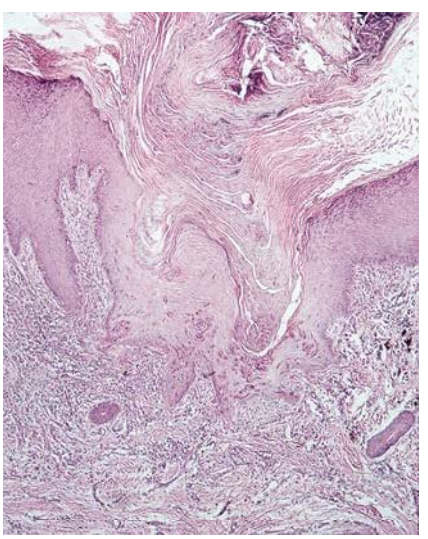


▲ **FIGURE 67-4** Reactive perforating collagenosis. Collagen bundles can be seen crossing from the reticular dermis through the epidermis into an epidermal depression containing necrotic debris. (Hematoxylin and eosin stain.)

More detailed histologic descriptions of Kyrle disease[22] report an invagination of the epidermis that is filled with a keratotic plug containing a parakeratotic column (Fig. 67-5). Within the epidermal invagination, there is a focus of vacuolated dyskeratotic cells, which extends to the basal cell layer and eventually penetrates into the dermis, leaving fragments of parakeratotic keratin in the dermis with a surrounding inflammatory and granulomatous reaction (see Fig. 67-5). Subsequent studies using Masson trichrome stains have found bundles of collagen perforating through the epidermis into the base of the invagination, suggesting an overlap with reactive perforating collagenosis.

Elastosis Perforans Serpiginosa

EPS is a unique perforating disorder characterized by transepidermal elimination of elastic fibers. The distinctive lesions are serpiginous in distribution and can be associated with specific diseases.



▲ **FIGURE 67-5** Kyrle disease. There is massive hyperkeratosis with a central parakeratotic column at the base of this column. Individual (apoptotic) cell keratinization can be followed down to the basal dermal epidermal junction.

HISTORY

ETIOLOGY AND PATHOGENESIS D-penicillamine appears to be a clear trigger for EPS. Alterations of elastic fibers have been described in patients with penicillamine-induced EPS, and this condition has usually occurred after long-term therapy of Wilson disease[34] or cystinuria. EPS has also been reported in a child treated with D-penicillamine for juvenile rheumatoid arthritis.[35] Abnormal elastic fibers have been found in the lungs as well as the skin of penicillamine-treated patients.[36] Abnormalities of collagen have also been described in patients with EPS.[37,38] The precise mechanism by which penicillamine induces EPS is not entirely known, but the drug chelates copper, the co-factor for lysyl oxidase, which is the enzyme that cross-links elastin.

Although most cases are sporadic, familial cases of EPS have been reported with different modes of inheritance. In at least one family, autosomal dominant inheritance with variable expression of EPS was suggested.[39] Several inherited disorders of connective tissue have also been associated with EPS (see Chap. 139), suggesting that various pathways can lead to the abnormal elastin that results in this condition.

CUTANEOUS LESIONS Skin lesions consist of hyperkeratotic papules ranging from 2 mm to 1 cm in diameter in a serpiginous distribution (Fig. 67-6). Skin within these serpiginous arcs is often atrophic. The most common site of involvement is the neck (see eFig. 67-6.1 in on-line edition), but lesions can also occur on the extremities and, more rarely, on the trunk. In rare instances, elastic tissue in the endocardium, bronchiolar walls, and arteries is involved. Rupture of the aorta has been reported.[40]

RELATED PHYSICAL FINDINGS EPS is associated with numerous inherited disorders, including osteogenesis imperfecta,[41] cutis laxa,[42] acrogeria,[43] Ehlers-Danlos syndrome, Marfan syndrome, Rothmund-Thomson syndrome,[44] and Down syndrome.[45] EPS has been reported in association with administration of D-penicillamine to treat Wilson disease (see eFig. 67-6.2 in on-line edition)[46] and with co-existing acquired cutis laxa after D-penicillamine therapy of cystinuria.[47]

HISTOPATHOLOGY Histologically, lesions are characterized by transepidermal elimination of elastic fibers. Typical changes can be identified and consist of an inflammatory response around abnormal elastic tissue in the papillary dermis. The elastic tissue penetrates through channels in the acanthotic epidermis. The channels may be straight or tortuous, and there may be multinucleated giant cells in the surrounding inflammatory infiltrate. In addition to elastic tissue, the channels contain necrobiotic material with degenerated epithelial cells and parakeratotic nuclei of inflammatory cells. The top of the epidermal channels is also filled with keratotic material.

▲ **FIGURE 67-6** Elastosis perforans serpiginosa. Erythematous, hyperkeratotic papules in a serpiginous distribution on the arm.

DIFFERENTIAL DIAGNOSIS (See Box 67-1)

The one entity easily confused with perforating diseases is prurigo nodularis. Other perforating disorders, such as perforating pseudoxanthoma elasticum (PXE) and perforating granuloma annulare, are easily distinguished from the acquired perforating disorders by skin biopsy.

Box 67-1

Differential Diagnosis of Acquired Perforating Disorders

- Perforating pseudoxanthoma elasticum
- Prurigo nodularis
- Excoriated dermal diseases (e.g., granuloma annulare, lichen planus)
- Hyperkeratosis follicularis perstans (Flegel disease)
- Acquired perforating dermatosis

Box 67-2

Treatment for Acquired Perforating Disorders

	TOPICAL	PHYSICAL	SYSTEMIC
First line	Corticosteroids	Broadband ultraviolet B Narrowband ultraviolet B	Acitretin, 30 mg daily Isotretinoin, 1 mg/kg in two divided doses daily
Second line	Retinoids	Psoralen and ultraviolet A light Surgical removal combined with oral clindamycin	Doxycycline, 100–200 mg daily in two divided doses; allopurinol, 100 mg daily

EPS is easily distinguished from other perforating disorders when characteristic serpiginous lesions are present (in contrast to individual papules in the latter) and by the finding of elastic fibers in the perforating tissue on histology. In contrast to the other perforating dermatoses, which are usually associated with diabetes or renal failure, EPS has an entirely different group of disease associations as mentioned in Elastosis Perforans Serpiginosa. There is a single case report of EPS in a patient with renal disease.[48] Histologically, however, the perforating elastic fibers of EPS usually allow differentiation, although fragments of elastic fibers may be found in the necrobiotic plug of other perforating disorders. At least one study reports the transepidermal elimination of elastic fibers in follicular occlusion disease, distinguishing that disorder from EPS.[49]

Individual lesions of perforating PXE can simulate those of the acquired perforating dermatoses, but patients with PXE have characteristic yellow papules and plaques on the neck, axillae, and other flexural sites (see Chap. 139). Moreover, on skin biopsy, von Kossa stains show calcification of elastic fibers, and Verhoeff-van Gieson stains show fragmentation and clumping of elastic tissue. There have, however, been cases of PXE with serpiginous perforating papules containing calcified elastic fibers, thus simulating EPS. The lesions of perforating granuloma annulare can also simulate acquired granuloma annulare, but on biopsy, palisading granulomas are seen (see Chap. 43). Flegel disease (hyperkeratosis follicularis perstans), a rare autosomal dominant genodermatosis, is also characterized by keratotic papules, but these are smaller and also involve the lower legs. Histologically, Flegel disease is not a perforating condition, but, occasionally, it has been confused with perforating disorders.[50]

PROGNOSIS, CLINICAL COURSE, AND TREATMENT

The perforating disorders are difficult to treat (Box 67-2). Their prognosis is tied to the underlying diseases, so treatment of the underlying cause can be effective. Although some have reported spontaneous disappearance of perforating disorders with stabilization of renal disease,[51] most of the perforating diseases continue for years unless treated. Perforating disorders frequently resolve after renal transplantation in patients with underlying kidney failure.[52] Although there are isolated reports of successful therapy using topical retinoids,[53–55] oral retinoids,[14,56,57] oral antibiotics (doxycycline[58,59] and clindamycin[60]), and allopurinol,[61–64] these are not usually effective. Phototherapy with narrowband ultraviolet B (UVB) or broadband UVB can result in substantial improvement,[40,65–68] but is not as reliably effective as phototherapy for uremic pruritus. UV light treatment, if successful, tends to require sessions two to three times per week with 10 to 15 exposures for clearance. Many of the treatments that have been applied to the other perforating disorders have also been used for EPS. Isotretinoin[69] and destructive modalities, such as cryotherapy[70] and lasers, have also been used effectively for EPS.[71,72]

Panniculitis

Panniculitis refers to inflammation of the subcutaneous fat. It is characterized by tender, erythematous nodules or plaques, usually on the lower legs. Histologically, there is inflammation of the fat lobules and septa.

Erythema nodosum

Erythema nodosum is the most common form of panniculitis. It is characterized by tender, erythematous nodules on the anterior aspects of the lower legs. Lesions may also occur on the thighs, arms, and trunk. Histologically, there is a septal panniculitis with a lymphocytic infiltrate and multinucleated giant cells.

Erythema induratum

Erythema induratum is a form of panniculitis that is associated with tuberculosis. It is characterized by tender, erythematous nodules on the lower legs. Histologically, there is a lobular panniculitis with granulomas and caseation necrosis.

Lupus panniculitis

Lupus panniculitis is a form of panniculitis that is associated with systemic lupus erythematosus. It is characterized by tender, erythematous nodules or plaques, usually on the face, trunk, and extremities. Histologically, there is a lobular panniculitis with a lymphocytic infiltrate and hyaline fat necrosis.

Pancreatic panniculitis

Pancreatic panniculitis is a form of panniculitis that is associated with pancreatic disease. It is characterized by tender, erythematous nodules or plaques, usually on the lower legs. Histologically, there is a lobular panniculitis with saponification of fat.

Sclerema neonatorum

Sclerema neonatorum is a rare form of panniculitis that occurs in newborns. It is characterized by diffuse, firm, waxy skin. Histologically, there is a lobular panniculitis with fat necrosis and fibrosis.

Subcutaneous fat necrosis of the newborn

Subcutaneous fat necrosis of the newborn is a form of panniculitis that occurs in newborns. It is characterized by tender, erythematous nodules or plaques, usually on the back, buttocks, and thighs. Histologically, there is a lobular panniculitis with fat necrosis and calcification.

Weber-Christian disease

Weber-Christian disease is a rare form of panniculitis that is characterized by recurrent episodes of tender, erythematous nodules or plaques, usually on the lower legs. Histologically, there is a lobular panniculitis with a lymphocytic infiltrate and fat necrosis.

Cold panniculitis

Cold panniculitis is a form of panniculitis that is caused by exposure to cold. It is characterized by tender, erythematous nodules or plaques, usually on the cheeks, nose, and chin. Histologically, there is a lobular panniculitis with fat necrosis and crystal formation.

Post-injection panniculitis

Post-injection panniculitis is a form of panniculitis that is caused by injection of medications or other substances into the subcutaneous tissue. It is characterized by tender, erythematous nodules or plaques at the injection site. Histologically, there is a lobular panniculitis with fat necrosis and a foreign body reaction.

Traumatic panniculitis

Traumatic panniculitis is a form of panniculitis that is caused by trauma to the subcutaneous tissue. It is characterized by tender, erythematous nodules or plaques at the site of trauma. Histologically, there is a lobular panniculitis with fat necrosis and hemorrhage.

Idiopathic panniculitis

Idiopathic panniculitis is a form of panniculitis that has no known cause. It is characterized by tender, erythematous nodules or plaques, usually on the lower legs. Histologically, there is a lobular panniculitis with a lymphocytic infiltrate and fat necrosis.

Treatment of panniculitis

Treatment of panniculitis depends on the underlying cause. Corticosteroids are often used to treat inflammatory forms of panniculitis. Other treatments may include immunosuppressants, antibiotics, and surgery.

Prognosis of panniculitis

The prognosis of panniculitis depends on the underlying cause. Most forms of panniculitis are self-limiting and resolve within a few weeks or months. However, some forms of panniculitis can be chronic and recurrent.

Complications of panniculitis

Complications of panniculitis may include infection, scarring, and deformity. Infection can occur if the skin is broken. Scarring can occur if the inflammation is severe. Deformity can occur if the fat necrosis is extensive.

Differential diagnosis of panniculitis

The differential diagnosis of panniculitis includes other conditions that can cause tender, erythematous nodules or plaques, such as cellulitis, erysipelas, and deep vein thrombosis.

Laboratory tests for panniculitis

Laboratory tests for panniculitis may include a complete blood count, erythrocyte sedimentation rate, and C-reactive protein. These tests can help to rule out infection and other systemic diseases.

Imaging studies for panniculitis

Imaging studies for panniculitis may include ultrasound, computed tomography, and magnetic resonance imaging. These studies can help to visualize the extent of the inflammation and fat necrosis.

Biopsy of panniculitis

A biopsy of panniculitis is the most definitive way to diagnose the condition. A biopsy can help to determine the underlying cause of the panniculitis and to rule out other conditions.

Histopathology of panniculitis

The histopathology of panniculitis depends on the underlying cause. However, most forms of panniculitis are characterized by inflammation of the fat lobules and septa, fat necrosis, and a lymphocytic infiltrate.

Immunopathology of panniculitis

The immunopathology of panniculitis depends on the underlying cause. However, most forms of panniculitis are characterized by the presence of T lymphocytes and macrophages in the inflammatory infiltrate.

Molecular pathology of panniculitis

The molecular pathology of panniculitis depends on the underlying cause. However, most forms of panniculitis are characterized by the expression of cytokines and chemokines that promote inflammation and fat necrosis.

Genetics of panniculitis

The genetics of panniculitis depends on the underlying cause. However, most forms of panniculitis are not inherited. Some forms of panniculitis may be associated with genetic mutations that affect the immune system or the metabolism of fat.

Epidemiology of panniculitis

The epidemiology of panniculitis depends on the underlying cause. However, most forms of panniculitis are relatively rare. Some forms of panniculitis may be more common in certain populations or geographic areas.

Risk factors for panniculitis

Risk factors for panniculitis depend on the underlying cause. However, most forms of panniculitis are not associated with any specific risk factors. Some forms of panniculitis may be associated with trauma, infection, or exposure to cold.

Prevention of panniculitis

Prevention of panniculitis depends on the underlying cause. However, most forms of panniculitis are not preventable. Some forms of panniculitis may be prevented by avoiding trauma, infection, or exposure to cold.

Patient education for panniculitis

Patient education for panniculitis should include information about the underlying cause of the condition, the treatment options, and the prognosis. Patients should also be instructed on how to avoid trauma, infection, and exposure to cold.

Research on panniculitis

Research on panniculitis is ongoing. Researchers are investigating the underlying causes of panniculitis, the most effective treatments, and the prognosis of different forms of panniculitis.

Future directions for panniculitis

Future directions for panniculitis include the development of new treatments, the identification of genetic risk factors, and the prevention of panniculitis.

Conclusion

Panniculitis is a group of inflammatory disorders that affect the subcutaneous fat. The underlying cause of panniculitis depends on the form of the disease. Treatment of panniculitis depends on the underlying cause. The prognosis of panniculitis depends on the underlying cause.

Melanocyte Physiology

Melanocytes are dendritic cells that produce melanin, a pigment that is responsible for the color of skin, hair, and eyes. Melanocytes are derived from neural crest cells and migrate to the epidermis, hair follicles, and other tissues during embryonic development. Melanocytes are found in the basal layer of the epidermis, where they are interspersed among keratinocytes. Melanocytes are also found in the hair follicle, where they are located in the bulge region and the hair bulb. Melanocytes are also found in the eye, where they are located in the iris, ciliary body, and choroid.

Melanocytes are responsible for the production of melanin, which is a complex polymer that is synthesized from the amino acid tyrosine. Melanin is produced in melanosomes, which are membrane-bound organelles that are found in the cytoplasm of melanocytes. Melanosomes are transferred to keratinocytes, where they are degraded and the melanin is released into the cytoplasm of keratinocytes. Melanin is then transported to the surface of the skin, where it is responsible for the color of skin, hair, and eyes.

Melanocytes are also responsible for the production of vitamin D. Vitamin D is produced in the skin when 7-dehydrocholesterol is converted to previtamin D3 by ultraviolet B radiation. Previtamin D3 is then converted to vitamin D3 by a thermal isomerization. Vitamin D3 is then converted to 25-hydroxyvitamin D3 by the liver and to 1,25-dihydroxyvitamin D3 by the kidney. 1,25-dihydroxyvitamin D3 is the active form of vitamin D.

Melanocytes are also responsible for the production of nitric oxide. Nitric oxide is produced in the skin when ultraviolet A radiation is absorbed by melanin. Nitric oxide is then released into the bloodstream, where it is responsible for the dilation of blood vessels. Nitric oxide is also responsible for the production of cyclic guanosine monophosphate (cGMP). cGMP is a second messenger that is responsible for the activation of protein kinase G (PKG). PKG is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of endothelin-1. Endothelin-1 is produced in the skin when ultraviolet A radiation is absorbed by melanin. Endothelin-1 is then released into the bloodstream, where it is responsible for the constriction of blood vessels. Endothelin-1 is also responsible for the production of cyclic guanosine monophosphate (cGMP). cGMP is a second messenger that is responsible for the activation of protein kinase G (PKG). PKG is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of α-melanocyte-stimulating hormone (α-MSH). α-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. α-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of adrenocorticotropic hormone (ACTH). ACTH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ACTH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of β-endorphin. β-endorphin is produced in the skin when ultraviolet A radiation is absorbed by melanin. β-endorphin is then released into the bloodstream, where it is responsible for the activation of opioid receptors. Opioid receptors are responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of γ-melanocyte-stimulating hormone (γ-MSH). γ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. γ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 3 receptor (MC3R). MC3R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of δ-melanocyte-stimulating hormone (δ-MSH). δ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. δ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 4 receptor (MC4R). MC4R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ζ-melanocyte-stimulating hormone (ζ-MSH). ζ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ζ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 5 receptor (MC5R). MC5R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of η-melanocyte-stimulating hormone (η-MSH). η-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. η-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 2 receptor (MC2R). MC2R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of θ-melanocyte-stimulating hormone (θ-MSH). θ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. θ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ι-melanocyte-stimulating hormone (ι-MSH). ι-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ι-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 3 receptor (MC3R). MC3R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of κ-melanocyte-stimulating hormone (κ-MSH). κ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. κ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 4 receptor (MC4R). MC4R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of λ-melanocyte-stimulating hormone (λ-MSH). λ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. λ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 5 receptor (MC5R). MC5R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of μ-melanocyte-stimulating hormone (μ-MSH). μ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. μ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ν-melanocyte-stimulating hormone (ν-MSH). ν-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ν-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 2 receptor (MC2R). MC2R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ξ-melanocyte-stimulating hormone (ξ-MSH). ξ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ξ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 3 receptor (MC3R). MC3R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ο-melanocyte-stimulating hormone (ο-MSH). ο-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ο-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 4 receptor (MC4R). MC4R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of π-melanocyte-stimulating hormone (π-MSH). π-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. π-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 5 receptor (MC5R). MC5R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ρ-melanocyte-stimulating hormone (ρ-MSH). ρ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ρ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of σ-melanocyte-stimulating hormone (σ-MSH). σ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. σ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 2 receptor (MC2R). MC2R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of τ-melanocyte-stimulating hormone (τ-MSH). τ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. τ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 3 receptor (MC3R). MC3R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of υ-melanocyte-stimulating hormone (υ-MSH). υ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. υ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 4 receptor (MC4R). MC4R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of φ-melanocyte-stimulating hormone (φ-MSH). φ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. φ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 5 receptor (MC5R). MC5R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of χ-melanocyte-stimulating hormone (χ-MSH). χ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. χ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ψ-melanocyte-stimulating hormone (ψ-MSH). ψ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ψ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 2 receptor (MC2R). MC2R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ω-melanocyte-stimulating hormone (ω-MSH). ω-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ω-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 3 receptor (MC3R). MC3R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of α-melanocyte-stimulating hormone (α-MSH). α-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. α-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of β-melanocyte-stimulating hormone (β-MSH). β-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. β-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 2 receptor (MC2R). MC2R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of γ-melanocyte-stimulating hormone (γ-MSH). γ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. γ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 3 receptor (MC3R). MC3R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of δ-melanocyte-stimulating hormone (δ-MSH). δ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. δ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 4 receptor (MC4R). MC4R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ε-melanocyte-stimulating hormone (ε-MSH). ε-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ε-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 5 receptor (MC5R). MC5R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ζ-melanocyte-stimulating hormone (ζ-MSH). ζ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ζ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of η-melanocyte-stimulating hormone (η-MSH). η-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. η-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 2 receptor (MC2R). MC2R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of θ-melanocyte-stimulating hormone (θ-MSH). θ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. θ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 3 receptor (MC3R). MC3R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ι-melanocyte-stimulating hormone (ι-MSH). ι-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ι-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 4 receptor (MC4R). MC4R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of κ-melanocyte-stimulating hormone (κ-MSH). κ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. κ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 5 receptor (MC5R). MC5R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of λ-melanocyte-stimulating hormone (λ-MSH). λ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. λ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of μ-melanocyte-stimulating hormone (μ-MSH). μ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. μ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 2 receptor (MC2R). MC2R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ν-melanocyte-stimulating hormone (ν-MSH). ν-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ν-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 3 receptor (MC3R). MC3R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ξ-melanocyte-stimulating hormone (ξ-MSH). ξ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ξ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 4 receptor (MC4R). MC4R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ο-melanocyte-stimulating hormone (ο-MSH). ο-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ο-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 5 receptor (MC5R). MC5R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of π-melanocyte-stimulating hormone (π-MSH). π-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. π-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ρ-melanocyte-stimulating hormone (ρ-MSH). ρ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ρ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 2 receptor (MC2R). MC2R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of σ-melanocyte-stimulating hormone (σ-MSH). σ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. σ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 3 receptor (MC3R). MC3R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of τ-melanocyte-stimulating hormone (τ-MSH). τ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. τ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 4 receptor (MC4R). MC4R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of υ-melanocyte-stimulating hormone (υ-MSH). υ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. υ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 5 receptor (MC5R). MC5R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of φ-melanocyte-stimulating hormone (φ-MSH). φ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. φ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 1 receptor (MC1R). MC1R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of χ-melanocyte-stimulating hormone (χ-MSH). χ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. χ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 2 receptor (MC2R). MC2R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ψ-melanocyte-stimulating hormone (ψ-MSH). ψ-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ψ-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 3 receptor (MC3R). MC3R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Melanocytes are also responsible for the production of ω-melanocyte-stimulating hormone (ω-MSH). ω-MSH is produced in the skin when ultraviolet A radiation is absorbed by melanin. ω-MSH is then released into the bloodstream, where it is responsible for the activation of melanocortin 4 receptor (MC4R). MC4R is responsible for the activation of adenylate cyclase. Adenylate cyclase is responsible for the production of cyclic adenosine monophosphate (cAMP). cAMP is a second messenger that is responsible for the activation of protein kinase A (PKA). PKA is responsible for the phosphorylation of proteins that are involved in the regulation of melanocyte proliferation and differentiation.

Vitiligo

Definition

Vitiligo is an acquired disorder of pigmentation characterized by depigmented macules and patches.

Epidemiology

Vitiligo affects 0.5–2% of the world's population. It is more common in dark-skinned individuals. Onset is usually before the age of 30 years.

Pathogenesis

Vitiligo is caused by the destruction of melanocytes. Several theories have been proposed to explain this destruction:

- Autoimmune theory: Vitiligo is associated with other autoimmune diseases, such as thyroid disease, pernicious anemia, and Addison's disease. Circulating antibodies to melanocytes have been found in some patients with vitiligo.
- Neural theory: Vitiligo may be caused by the release of a neurotransmitter that is toxic to melanocytes.
- Self-destruction theory: Melanocytes may be destroyed by their own metabolic products.

Clinical features

Vitiligo presents as depigmented macules and patches. The lesions are usually symmetrical and may involve any part of the body. The hair in the affected areas may also be depigmented.

▲ Vitiligo. Depigmented macules and patches on the arm.

Diagnosis

The diagnosis of vitiligo is usually made on clinical grounds. A Wood's lamp examination may be helpful in confirming the diagnosis.

Differential diagnosis

- Pityriasis alba
- Tinea versicolor
- Leprosy
- Chemical leukoderma

Management

There is no cure for vitiligo. Treatment options include:

- Topical corticosteroids
- Topical calcineurin inhibitors
- Phototherapy
- Depigmentation therapy

Albinism

Definition

Albinism is a group of inherited disorders characterized by a reduction or absence of melanin pigment in the skin, hair, and eyes.

Epidemiology

Albinism affects approximately 1 in 17,000 people worldwide. It is more common in certain populations, such as the Hopi Indians of Arizona.

Pathogenesis

Albinism is caused by mutations in genes that are involved in the production of melanin. The most common form of albinism is oculocutaneous albinism type 1 (OCA1), which is caused by mutations in the tyrosinase gene.

Clinical features

Albinism presents with a reduction or absence of melanin pigment in the skin, hair, and eyes. Affected individuals may also have visual impairment, nystagmus, and photophobia.

Diagnosis

The diagnosis of albinism is usually made on clinical grounds. Genetic testing may be helpful in confirming the diagnosis.

Management

There is no cure for albinism. Management is supportive and includes:

- Protection from the sun
- Visual aids
- Genetic counseling

Oral Mucosal Lesions

Aphthous Ulcers

Aphthous ulcers are common, painful, recurrent ulcers of the oral mucosa. They are also known as canker sores. Aphthous ulcers are classified as minor, major, or herpetiform. Minor aphthous ulcers are the most common type. They are small, round or oval ulcers with a yellow-gray base and a red halo. They usually heal within 10 to 14 days without scarring. Major aphthous ulcers are larger, deeper, and more painful than minor aphthous ulcers. They can take several weeks to heal and may leave scars. Herpetiform aphthous ulcers are the least common type. They are small, shallow ulcers that appear in clusters of 10 to 100. They usually heal within 7 to 10 days without scarring.

The exact cause of aphthous ulcers is unknown. However, they are thought to be triggered by a combination of factors, including stress, trauma, certain foods, and hormonal changes. Aphthous ulcers are also more common in people with certain autoimmune diseases, such as Crohn disease and celiac disease.

Treatment for aphthous ulcers is usually symptomatic. Topical corticosteroids, such as triamcinolone acetonide, can help to reduce pain and inflammation. Topical anesthetics, such as lidocaine, can also help to relieve pain. In severe cases, systemic corticosteroids or immunosuppressants may be necessary.

Herpes Simplex Virus Infections

Herpes simplex virus infections are caused by the herpes simplex virus (HSV). There are two types of HSV: HSV-1 and HSV-2. HSV-1 is usually associated with oral herpes infections, while HSV-2 is usually associated with genital herpes infections. However, either type can cause infections in either location.

Oral herpes infections can cause a variety of symptoms, including fever blisters, cold sores, and gingivostomatitis. Fever blisters and cold sores are small, fluid-filled blisters that appear on the lips or around the mouth. Gingivostomatitis is a more severe infection that can cause pain, swelling, and difficulty eating and drinking.

Genital herpes infections can cause a variety of symptoms, including painful blisters, ulcers, and itching. The blisters and ulcers can appear on the genitals, buttocks, or thighs. Genital herpes infections can also cause flu-like symptoms, such as fever, headache, and muscle aches.

There is no cure for herpes simplex virus infections. However, antiviral medications can help to reduce the severity and duration of outbreaks. Antiviral medications can also help to prevent transmission of the virus to others.

Candidiasis

Candidiasis is a fungal infection caused by Candida albicans. It can occur in the mouth, throat, vagina, or skin. Oral candidiasis is also known as thrush. It is characterized by white patches on the tongue, inner cheeks, and roof of the mouth. These patches can be painful and may bleed when scraped.

Vaginal candidiasis is also known as a yeast infection. It is characterized by itching, burning, and a thick, white discharge. Candidiasis of the skin can occur in any moist area of the body, such as the armpits, groin, or under the breasts. It is characterized by a red, itchy rash.

Candidiasis is usually treated with antifungal medications. These medications can be applied topically or taken orally. In severe cases, intravenous antifungal medications may be necessary.

Leukoplakia

Leukoplakia is a white patch or plaque that appears on the oral mucosa. It is usually caused by chronic irritation, such as from tobacco use or ill-fitting dentures. Leukoplakia can also be caused by certain medications, such as chemotherapy drugs.

Leukoplakia is usually painless, but it can become painful if it becomes infected or ulcerated. It is important to have leukoplakia evaluated by a dentist or doctor, as it can be a precancerous lesion.

Treatment for leukoplakia depends on the underlying cause. If the leukoplakia is caused by chronic irritation, the irritant should be removed. If the leukoplakia is caused by a medication, the medication should be discontinued. In some cases, surgical removal of the leukoplakia may be necessary.

Oral Cancer

Oral cancer is a cancer that develops in the oral cavity. It can occur in the lips, tongue, cheeks, floor of the mouth, hard palate, or soft palate. Oral cancer is usually caused by tobacco use, alcohol use, or both. It can also be caused by human papillomavirus (HPV) infection.

Oral cancer can cause a variety of symptoms, including a sore that does not heal, a lump or thickening in the mouth, pain in the mouth or throat, difficulty swallowing, and numbness in the mouth or tongue. Oral cancer can be diagnosed by a biopsy, which is the removal of a small piece of tissue for examination under a microscope.

Treatment for oral cancer depends on the stage of the cancer. Surgery, radiation therapy, and chemotherapy are all used to treat oral cancer. The prognosis for oral cancer is generally good if it is detected early.

Genital Mucosal Lesions

Genital Herpes

Genital herpes is a sexually transmitted infection caused by herpes simplex virus (HSV). There are two types of HSV: HSV-1 and HSV-2. HSV-1 is usually associated with oral herpes infections, while HSV-2 is usually associated with genital herpes infections. However, either type can cause infections in either location.

Genital herpes infections can cause a variety of symptoms, including painful blisters, ulcers, and itching. The blisters and ulcers can appear on the genitals, buttocks, or thighs. Genital herpes infections can also cause flu-like symptoms, such as fever, headache, and muscle aches.

There is no cure for genital herpes infections. However, antiviral medications can help to reduce the severity and duration of outbreaks. Antiviral medications can also help to prevent transmission of the virus to others.

Genital Warts

Genital warts are caused by human papillomavirus (HPV). There are many types of HPV, but only a few of them cause genital warts. Genital warts are usually painless, but they can be itchy or irritating. They can appear on the genitals, anus, or mouth.

Genital warts can be diagnosed by a visual examination. Treatment for genital warts depends on the size and location of the warts. Topical medications, such as imiquimod and podophyllin, can be applied to the warts. Cryotherapy, which is the freezing of the warts, can also be used. In some cases, surgical removal of the warts may be necessary.

Syphilis

Syphilis is a sexually transmitted infection caused by Treponema pallidum. It is characterized by a painless sore, called a chancre, that appears at the site of infection. Syphilis can also cause a rash, fever, and swollen lymph nodes.

Syphilis can be diagnosed by a blood test. Treatment for syphilis is usually with penicillin. In severe cases, intravenous penicillin may be necessary.

Chancroid

Chancroid is a sexually transmitted infection caused by Haemophilus ducreyi. It is characterized by painful ulcers on the genitals. Chancroid can also cause swollen lymph nodes.

Chancroid can be diagnosed by a culture of the ulcer. Treatment for chancroid is usually with antibiotics. In severe cases, intravenous antibiotics may be necessary.

Lymphogranuloma Venereum

Lymphogranuloma venereum is a sexually transmitted infection caused by Chlamydia trachomatis. It is characterized by painful ulcers on the genitals. Lymphogranuloma venereum can also cause swollen lymph nodes.

Lymphogranuloma venereum can be diagnosed by a culture of the ulcer. Treatment for lymphogranuloma venereum is usually with antibiotics. In severe cases, intravenous antibiotics may be necessary.

Vulvar Cancer

Vulvar cancer is a rare cancer that usually occurs in women over the age of 50 years. Most vulvar cancers are squamous cell carcinomas. Other types include melanoma, adenocarcinoma, basal cell carcinoma, and sarcoma.

Risk Factors

Risk factors for vulvar cancer include:

- Human papillomavirus (HPV) infection
- Vulvar intraepithelial neoplasia (VIN)
- Lichen sclerosus
- Smoking
- Immunosuppression
- Chronic vulvar irritation

Symptoms

Symptoms of vulvar cancer include:

- Persistent vulvar itching
- Pain or burning
- A lump or sore that does not heal
- Bleeding not related to menstruation
- Changes in the color or texture of the skin

Diagnosis

Diagnosis is made by biopsy of the suspicious lesion. Staging is based on the FIGO system and depends on tumor size, depth of invasion, lymph node involvement, and distant metastasis.

Treatment

Treatment options include:

- Surgical excision (wide local excision or radical vulvectomy)
- Inguinal lymphadenectomy
- Radiation therapy
- Chemotherapy

Vaginal Cancer

Vaginal cancer is also rare. Squamous cell carcinoma is the most common type. Adenocarcinoma, especially clear cell adenocarcinoma, may occur in women exposed to diethylstilbestrol (DES) in utero.

Risk Factors

- HPV infection
- Cervical intraepithelial neoplasia (CIN)
- Prior pelvic radiation
- DES exposure
- Smoking

Symptoms

- Vaginal bleeding
- Watery discharge
- Pain
- A palpable mass

Diagnosis and Treatment

Diagnosis is by biopsy. Treatment depends on stage and may include radiation therapy, chemotherapy, or surgical excision.

Cervical Cancer

Cervical cancer is one of the most common cancers in women worldwide. Nearly all cervical cancers are caused by persistent infection with high-risk types of HPV.

Risk Factors

- HPV infection
- Cervical intraepithelial neoplasia (CIN)
- Smoking
- Immunosuppression
- Multiple sexual partners
- Early sexual activity
- Low socioeconomic status

Symptoms

- Abnormal vaginal bleeding
- Postcoital bleeding
- Watery or bloody discharge
- Pelvic pain
- Dyspareunia

Diagnosis

Diagnosis is made by Pap smear and colposcopy with biopsy. Staging is based on the FIGO system and depends on tumor size, depth of invasion, lymph node involvement, and distant metastasis.

Treatment

Treatment options include:

- Surgical excision (cone biopsy, simple hysterectomy, radical hysterectomy)
- Radiation therapy
- Chemotherapy

Uterine Cancer

Uterine cancer includes endometrial cancer and uterine sarcoma. Endometrial cancer is the most common gynecologic cancer in the United States.

Risk Factors

- Unopposed estrogen exposure
- Obesity
- Diabetes mellitus
- Hypertension
- Nulliparity
- Late menopause
- Tamoxifen use
- Lynch syndrome

Symptoms

- Abnormal vaginal bleeding
- Postmenopausal bleeding
- Watery discharge
- Pelvic pain

Diagnosis

Diagnosis is made by endometrial biopsy or dilation and curettage. Staging is based on the FIGO system and depends on tumor size, depth of invasion, lymph node involvement, and distant metastasis.

Treatment

Treatment options include:

- Surgical excision (total hysterectomy and bilateral salpingo-oophorectomy)
- Radiation therapy
- Chemotherapy
- Hormonal therapy

Ovarian Cancer

Ovarian cancer is the most lethal gynecologic cancer. Most ovarian cancers are epithelial tumors. Germ cell tumors and sex cord-stromal tumors are rare.

Risk Factors

- Nulliparity
- Late menopause
- Family history of ovarian, breast, or colorectal cancer
- BRCA1 and BRCA2 mutations
- Lynch syndrome
- Talc exposure

Symptoms

- Abdominal bloating
- Pelvic pain
- Early satiety
- Urinary frequency
- Constipation
- Weight loss

Diagnosis

Diagnosis is made by imaging and biopsy. Staging is based on the FIGO system and depends on tumor size, depth of invasion, lymph node involvement, and distant metastasis.

Treatment

Treatment options include:

- Surgical excision (total hysterectomy and bilateral salpingo-oophorectomy)
- Chemotherapy
- Radiation therapy
- Hormonal therapy

Fallopian Tube Cancer

Fallopian tube cancer is rare. Most fallopian tube cancers are epithelial tumors.

Risk Factors

- Nulliparity
- Late menopause
- Family history of ovarian, breast, or colorectal cancer
- BRCA1 and BRCA2 mutations
- Lynch syndrome

Symptoms

- Abdominal bloating
- Pelvic pain
- Early satiety
- Urinary frequency
- Constipation
- Weight loss

Diagnosis

Diagnosis is made by imaging and biopsy. Staging is based on the FIGO system and depends on tumor size, depth of invasion, lymph node involvement, and distant metastasis.

Treatment

Treatment options include:

- Surgical excision (total hysterectomy and bilateral salpingo-oophorectomy)
- Chemotherapy
- Radiation therapy
- Hormonal therapy

Gestational Trophoblastic Disease

Gestational trophoblastic disease includes hydatidiform mole, invasive mole, choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor.

Risk Factors

- Extremes of maternal age
- Prior molar pregnancy
- Blood group A

Symptoms

- Abnormal vaginal bleeding
- Uterine enlargement
- Hyperemesis gravidarum
- Hyperthyroidism
- Theca lutein cysts

Diagnosis

Diagnosis is made by human chorionic gonadotropin (hCG) measurement and imaging. Staging is based on the FIGO system and depends on tumor size, depth of invasion, lymph node involvement, and distant metastasis.

Treatment

Treatment options include:

- Surgical excision (dilation and curettage, hysterectomy)
- Chemotherapy
- Radiation therapy

Sebaceous Glands

Introduction

Sebaceous glands are found in the skin of all mammals except for the cetaceans (whales, dolphins, and porpoises) and the sirenians (manatees and dugongs). They are also found in the mucosa of the eyelids, the mucocutaneous junctions of the genitalia, and the mucosa of the oral cavity. Sebaceous glands are holocrine glands that secrete a lipid-rich material called sebum. Sebum is composed of triglycerides, free fatty acids, wax esters, squalene, cholesterol esters, and cholesterol. Sebum is thought to have a number of functions, including lubrication of the skin and hair, antimicrobial activity, and waterproofing. Sebaceous glands are usually associated with hair follicles, and they empty into the follicle just above the point where the arrector pili muscle inserts into the follicle. Sebaceous glands are also found in areas of skin that do not have hair follicles, such as the lips, the glans penis, the inner surface of the prepuce, and the labia minora. These glands are called modified sebaceous glands or sebaceous glands of specialized areas. Sebaceous glands are also found in the mucosa of the eyelids, the mucocutaneous junctions of the genitalia, and the mucosa of the oral cavity. These glands are called sebaceous glands of mucous membranes.

Development

Sebaceous glands develop from the epithelial cells of the hair follicle. The first sebaceous glands appear during the fetal period, and they continue to develop throughout life. The development of sebaceous glands is regulated by a number of factors, including androgens, estrogens, and progesterone. Androgens stimulate the development of sebaceous glands, while estrogens and progesterone inhibit their development. The development of sebaceous glands is also regulated by a number of other factors, including growth factors, cytokines, and neuropeptides.

Structure

Sebaceous glands are composed of a number of lobules, each of which is composed of a number of acini. The acini are lined by a single layer of epithelial cells. The epithelial cells are polyhedral in shape and have a large nucleus. The cytoplasm of the epithelial cells is filled with lipid droplets. The lipid droplets are surrounded by a membrane. The membrane is composed of a phospholipid bilayer. The lipid droplets are released into the lumen of the acini when the epithelial cells undergo holocrine secretion. The lumen of the acini is connected to the hair follicle by a short duct. The duct is lined by a single layer of epithelial cells. The epithelial cells are cuboidal in shape and have a small nucleus. The cytoplasm of the epithelial cells is filled with keratin filaments. The keratin filaments are surrounded by a membrane. The membrane is composed of a phospholipid bilayer. The keratin filaments are released into the lumen of the duct when the epithelial cells undergo holocrine secretion. The lumen of the duct

Acne Vulgaris

Epidemiology

Acne vulgaris affects nearly all adolescents to some degree. Although it is most common in teenagers, it can occur in children younger than 10 years of age and in adults older than 40 years of age. Acne is more severe in males than in females, and it tends to be more severe and persistent in African Americans than in Caucasians.

Pathogenesis

Acne vulgaris is a disease of the pilosebaceous unit, which consists of a hair follicle and its associated sebaceous gland. Androgens stimulate sebaceous gland growth and sebum production. Sebum, keratinocytes, and bacteria (*Propionibacterium acnes*) fill the follicle, causing it to dilate and form a comedo. Inflammation develops around the follicle, leading to papules, pustules, and nodules.

Clinical Manifestations

Acne vulgaris is characterized by comedones, papules, pustules, nodules, and cysts. Comedones are the primary lesions and may be open (blackheads) or closed (whiteheads). Inflammatory lesions develop around comedones. Scarring may occur with severe inflammation.

Diagnostic Findings

Acne vulgaris is diagnosed clinically based on the presence of comedones and inflammatory lesions. Laboratory tests are not usually necessary.

Therapeutic Management

Treatment of acne vulgaris depends on the severity of the disease. Mild acne is treated with topical agents, such as benzoyl peroxide, topical retinoids, and topical antibiotics. Moderate acne may require the addition of oral antibiotics. Severe acne may require oral isotretinoin (Accutane). Hormonal therapy with oral contraceptives may be helpful in females.

Nursing Management

Nursing management includes teaching the patient about the disease process, medications, and skin care. The patient should be instructed to wash the face gently with a mild soap and water, avoid picking or squeezing lesions, and use medications as prescribed. The patient should be informed that it may take several weeks to see improvement.

Rosacea

Epidemiology

Rosacea is a chronic inflammatory disease of the face that primarily affects adults between the ages of 30 and 50 years. It is more common in females than in males, and it is more common in Caucasians than in African Americans.

Pathogenesis

The pathogenesis of rosacea is not well understood. It is thought to be related to vascular dysfunction, immune dysfunction, and the presence of *Demodex* mites.

Clinical Manifestations

Rosacea is characterized by erythema, telangiectasia, papules, pustules, and rhinophyma. It typically affects the central face, including the cheeks, nose, chin, and forehead.

Diagnostic Findings

Rosacea is diagnosed clinically based on the presence of characteristic lesions.

Therapeutic Management

Treatment of rosacea includes topical metronidazole, oral antibiotics, and laser therapy. Avoidance of triggers, such as sun exposure, hot beverages, and spicy foods, is also important.

Nursing Management

Nursing management includes teaching the patient about the disease process, medications, and skin care. The patient should be instructed to avoid triggers, use sunscreen, and use medications as prescribed.

Seborrheic Dermatitis

Epidemiology

Seborrheic dermatitis is a common inflammatory skin disease that affects infants, adolescents, and adults. It is more common in males than in females.

Pathogenesis

The pathogenesis of seborrheic dermatitis is not well understood. It is thought to be related to the presence of *Malassezia* yeast and immune dysfunction.

Clinical Manifestations

Seborrheic dermatitis is characterized by erythema, scaling, and pruritus. It typically affects the scalp, face, and trunk.

Diagnostic Findings

Seborrheic dermatitis is diagnosed clinically based on the presence of characteristic lesions.

Therapeutic Management

Treatment of seborrheic dermatitis includes topical corticosteroids, topical antifungals, and topical calcineurin inhibitors.

Nursing Management

Nursing management includes teaching the patient about the disease process, medications, and skin care. The patient should be instructed to use medications as prescribed and avoid triggers.

Psoriasis

Epidemiology

Psoriasis is a chronic inflammatory skin disease that affects approximately 2% of the population. It can occur at any age, but it most commonly begins between the ages of 15 and 35 years. It is more common in Caucasians than in African Americans.

Pathogenesis

Psoriasis is an immune-mediated disease characterized by hyperproliferation of keratinocytes and inflammation. Genetic factors play a role in the development of psoriasis.

Clinical Manifestations

Psoriasis is characterized by well-demarcated, erythematous plaques covered with silvery scales. It typically affects the extensor surfaces of the elbows and knees, the scalp, and the trunk.

Diagnostic Findings

Psoriasis is diagnosed clinically based on the presence of characteristic lesions. A skin biopsy may be performed to confirm the diagnosis.

Therapeutic Management

Treatment of psoriasis depends on the severity of the disease. Mild psoriasis is treated with topical agents, such as corticosteroids, vitamin D analogs, and topical retinoids. Moderate to severe psoriasis may require phototherapy or systemic therapy with methotrexate, cyclosporine, or biologic agents.

Nursing Management

Nursing management includes teaching the patient about the disease process, medications, and skin care. The patient should be instructed to avoid triggers, such as stress, infection, and certain medications, and to use medications as prescribed.

Hyperhidrosis

Hyperhidrosis is excessive sweating that is more than what is required for normal thermoregulation. Primary hyperhidrosis is a disorder of the eccrine sweat glands that is localized to the palms, soles, axillae, and face. Secondary hyperhidrosis is generalized sweating that is caused by a medical condition, medication, or substance.

Epidemiology

Primary hyperhidrosis affects 1% to 3% of the population. Men and women are affected equally. Onset is usually in childhood or adolescence. Secondary hyperhidrosis can occur at any age.

Pathophysiology

Primary hyperhidrosis is caused by overactivity of the sympathetic nervous system. Secondary hyperhidrosis is caused by a variety of conditions, including infections, endocrine disorders, neurologic disorders, and malignancies.

Clinical Features

Patients with primary hyperhidrosis have sweating that is bilateral and symmetric. The sweating is not related to heat or exercise. It can be embarrassing and can interfere with social and occupational activities.

Diagnosis

The diagnosis of primary hyperhidrosis is made clinically. Secondary hyperhidrosis is diagnosed by identifying the underlying cause.

Treatment

Treatment of primary hyperhidrosis includes topical antiperspirants, iontophoresis, botulinum toxin injections, and surgery. Treatment of secondary hyperhidrosis is directed at the underlying cause.

Bromhidrosis

Bromhidrosis is a disorder of the apocrine sweat glands that is characterized by malodorous sweat. It is caused by the bacterial decomposition of apocrine sweat.

Epidemiology

Bromhidrosis is common in adolescents and young adults. It is more common in men than in women.

Pathophysiology

Apocrine sweat is odorless when it is secreted. It becomes malodorous when it is decomposed by bacteria on the skin surface.

Clinical Features

Patients with bromhidrosis have a strong, unpleasant odor that is most noticeable in the axillae, groin, and feet. The odor can be embarrassing and can interfere with social and occupational activities.

Diagnosis

The diagnosis of bromhidrosis is made clinically.

Treatment

Treatment of bromhidrosis includes topical antiperspirants, antibiotics, and surgery.

Chromhidrosis

Chromhidrosis is a disorder of the apocrine sweat glands that is characterized by colored sweat. It is caused by the presence of pigment in apocrine sweat.

Epidemiology

Chromhidrosis is rare. It can occur at any age.

Pathophysiology

Apocrine sweat is normally colorless. It becomes colored when it contains pigment.

Clinical Features

Patients with chromhidrosis have colored sweat that is most noticeable in the axillae, groin, and feet. The color can be blue, green, yellow, or red.

Diagnosis

The diagnosis of chromhidrosis is made clinically.

Treatment

Treatment of chromhidrosis includes topical antiperspirants and surgery.

Miliaria

Miliaria is a disorder of the eccrine sweat glands that is characterized by small, pruritic papules. It is caused by the obstruction of eccrine sweat ducts.

Epidemiology

Miliaria is common in infants and young children. It is more common in hot, humid climates.

Pathophysiology

Eccrine sweat ducts are obstructed by keratin plugs. The obstruction causes sweat to leak into the surrounding tissue.

Clinical Features

Patients with miliaria have small, pruritic papules that are most noticeable in the axillae, groin, and feet. The papules can be red, white, or clear.

Diagnosis

The diagnosis of miliaria is made clinically.

Treatment

Treatment of miliaria includes topical antiperspirants and antibiotics.

Pachyonychia Congenita

Pachyonychia congenita is a rare genetic disorder that is characterized by thickened nails and palmoplantar keratoderma. It is caused by mutations in keratin genes.

Epidemiology

Pachyonychia congenita is rare. It can occur at any age.

Pathophysiology

Pachyonychia congenita is caused by mutations in keratin genes. The mutations cause abnormal keratin production.

Clinical Features

Patients with pachyonychia congenita have thickened nails and palmoplantar keratoderma. The nails can be yellow, brown, or black.

Diagnosis

The diagnosis of pachyonychia congenita is made clinically.

Treatment

Treatment of pachyonychia congenita includes topical keratolytics and systemic retinoids.

Anatomy and Physiology

The eccrine sweat glands are found in the skin of all areas of the body, with the highest density on the palms and soles. Each gland consists of a coiled secretory portion in the dermis and a duct that opens directly onto the skin surface. Sweat is produced in response to thermal stimulation and emotional stress, and is primarily composed of water and electrolytes.

Hyperhidrosis

Hyperhidrosis is excessive sweating beyond what is required for thermoregulation. It can be localized to the palms, soles, axillae, or face, or it can be generalized. Primary hyperhidrosis has no identifiable underlying cause and typically begins in childhood or adolescence. Secondary hyperhidrosis may be associated with endocrine disorders, infections, or medications.

Treatment

Treatment options include topical aluminum chloride, botulinum toxin injections, iontophoresis, and in refractory cases, surgical sympathectomy. The choice of therapy depends on the severity of symptoms and the patient's quality of life.

Bromhidrosis

Bromhidrosis is malodorous sweat resulting from the bacterial decomposition of sweat, particularly in the apocrine-rich axillae and groin. Eccrine bromhidrosis can occur on the palms and soles.

Chromhidrosis

Chromhidrosis refers to colored sweat. Examples include blue sweat, yellow sweat, and black sweat. The color may be due to pigments produced by bacteria or to pigments excreted by the glands themselves.

Miliaria

Miliaria, or prickly heat, results from obstruction of the eccrine sweat ducts. Depending on the level of obstruction, it may present as crystalline, rubra, pustulosa, or profunda miliaria.

Hyperhidrosis

Hyperhidrosis is excessive sweating that is not related to heat or exercise. It is a common problem that affects approximately 1% of the population. Hyperhidrosis can be localized to the axillae, palms, soles, face, or groin, or it can be generalized. Localized hyperhidrosis usually begins in childhood or adolescence and is often familial. Generalized hyperhidrosis usually begins in adulthood and is rarely familial.

Pathophysiology

Hyperhidrosis is caused by overactivity of the eccrine sweat glands. The eccrine sweat glands are innervated by the sympathetic nervous system, which is responsible for the fight-or-flight response. In hyperhidrosis, the sympathetic nervous system is overactive, even at rest.

Clinical Features

Hyperhidrosis is characterized by excessive sweating that is not related to heat or exercise. The sweating can be so severe that it interferes with daily activities. Patients with hyperhidrosis may also have skin infections, such as bacterial or fungal infections, because the excessive moisture creates a favorable environment for these organisms.

Diagnosis

The diagnosis of hyperhidrosis is usually made clinically. The patient's history and physical examination are usually sufficient to make the diagnosis. Laboratory tests are not usually necessary.

Treatment

Treatment of hyperhidrosis depends on the severity of the condition. Mild cases can be treated with topical antiperspirants. Moderate to severe cases can be treated with botulinum toxin injections, iontophoresis, or oral medications. Surgical treatment is reserved for severe, refractory cases.

Bromhidrosis

Bromhidrosis is a condition characterized by foul-smelling sweat. It is caused by the bacterial decomposition of sweat. Bromhidrosis can be localized to the axillae, feet, or groin, or it can be generalized.

Pathophysiology

Bromhidrosis is caused by the bacterial decomposition of sweat. The bacteria that cause bromhidrosis are usually found on the skin. They break down the components of sweat, producing foul-smelling odors.

Clinical Features

Bromhidrosis is characterized by foul-smelling sweat. The odor can be so severe that it interferes with daily activities. Patients with bromhidrosis may also have skin infections, such as bacterial or fungal infections, because the excessive moisture creates a favorable environment for these organisms.

Diagnosis

The diagnosis of bromhidrosis is usually made clinically. The patient's history and physical examination are usually sufficient to make the diagnosis. Laboratory tests are not usually necessary.

Treatment

Treatment of bromhidrosis depends on the severity of the condition. Mild cases can be treated with topical antiperspirants. Moderate to severe cases can be treated with botulinum toxin injections, iontophoresis, or oral medications. Surgical treatment is reserved for severe, refractory cases.

SECTION 15

DISORDERS OF THE HAIR AND NAILS

CHAPTER 84

Biology of Hair Follicles

George Cotsarelis
Vladimir Botchkarev

EVOLUTION AND FUNCTION OF HAIR

Hair is found only in mammals, where during the course of evolution its primary roles were to serve as insulation and protection from the elements. In contemporary humans, however, hair's main purpose revolves around its profound role in social interactions. Loss of hair (alopecia) and excessive hair growth in unwanted areas (hirsutism and hypertrichosis) can lead to significant psychological and emotional distress that supports a multibillion-dollar effort to reverse these conditions.

Much progress has been made in understanding hair growth, and as a result new treatments for alopecia are on the horizon.[1,2] These advances resulted from the interest of developmental biologists and other investigators in the hair follicle as a model for a wide range of biologic processes. As each hair follicle cyclically regenerates, it recapitulates its initial development. Many growth factors and receptors important during hair follicle development also regulate hair follicle cycling.[3–10] The hair follicle possesses keratinocyte and melanocyte stem cells (MSCs), nerves, and vasculature that are important in healthy and diseased skin.[11–13] To appreciate this emerging information and to properly assess a patient with hair loss or excess hair, an understanding of the anatomy and development of the hair follicle is essential.

EMBRYOLOGY

Morphologically, hair follicle development has been divided into eight consecutive stages, several of which are illustrated in Fig. 84-1. Each stage is characterized by unique expression patterns for growth factors and their receptors, growth factor antagonists, adhesion molecules, and intracellular signal transduction components.[14–16] Promising advances in understanding the molecular mechanisms behind hair follicle development arose through the discovery that mammalian counterparts (homologues) of genes important for normal *Drosophila* (fruit fly) development also affect hair follicle development. *Decapentaplegic [Dpp/bone morphogenetic protein (BMP)], Engrailed (en), Homeobox (hox), hedgehog/patched (hh/ptc), notch, wingless/armadillo (wg/wnt/catenin)* genes are all critical for hair follicle and vertebrate development in general (reviewed in refs. 17–19). These genes were all first discovered in *Drosophila*, thus, most of the names assigned to them describe the peculiar appearance (phenotype) of the flies carrying mutations in these genes.[19a]

Follicle formation begins on the head, and then moves downward to the remainder of the body in utero. The first hairs formed are lanugo hairs, which are non-pigmented, soft, and fine. Lanugo hair is typically shed between the thirty-second and thirty-sixth weeks, although approximately one-third of newborns still retain their lanugo hair for up to several weeks after birth.

Patterning genes, called *homeobox genes*, which are precisely organized in the genome so that they are expressed in strict temporal sequences and spatial patterns during development, likely are responsible for the nonrandom and symmetric distribution of hair follicles over the body.[20,21] In adult mice, homeobox gene expression reappears in hair follicles and serves to maintain normal hair shaft production.[6] *Engrailed*, a type of homeobox gene, is responsible for dorsal-ventral patterning, and mice lacking *engrailed* develop hair follicles on their footpads.[22]

Although hair follicles and hairs all share the same basic anatomy, their growth, size, shape, pigmentation, and other characteristics differ widely, based on body location and variation among

BIOLOGY OF HAIR FOLLICLES AT A GLANCE

- The primary purpose of hair in humans is to influence social interactions.
- Hair follicle development depends on interactions between epithelial and mesenchymal cells. The genes important for this interaction are slowly being elucidated.
- Genes important for hair follicle development also play a role in hair follicle cycling.
- The hair follicle bulge possesses stem cells important for the continual regeneration of the follicle during cycling.
- Hair pigmentation depends on melanocyte stem cells and differentiated cells in the follicle. Many genes important for melanocyte behavior and hair pigmentation have been defined.

BMP = bone morphogenetic protein; BMPR-IA = bone morphogenetic protein receptor, type IA CK = keratin 5; Cutl1 = cut-like 1; E-cadherin = epithelial cadherin; EDA = ectodysplasin; EDAR = ectodysplasin receptor; EGFR = epidermal growth factor receptor; Foxn1 = forkhead box N1; Gata3 = GATA binding protein 3; Gli1 = glioma-associated oncogene homolog 1; HGF = hepatocyte growth factor; Hoxc13 = homeobox C13; KGF = keratinocyte growth factor; Lef-1 = lymphoid enhancer factor 1; Lhx2 = LIM homeobox 2; N-CAM = neural cell adhesion molecule; P-cadherin = placental cadherin; PDGF-α = platelet-derived growth factor α polypeptide; PFGF-Rα = platelet-derived growth factor receptor α; Ptc1 = patched1; SCF = stem cell factor; Shh = sonic hedgehog; TCF3 = transcription factor 3; TGF-βR-II = transforming growth factor-β receptor 2.

individuals. Many of these characteristics are established during development but are then profoundly altered by hormonal influences later in life. Little is known about which genes determine hair curliness, length, volume, and appearance or which genes are responsible for conversion of one size follicle to another. Phenotypic changes in size within the same follicle occur several times throughout life. For example, lanugo hairs, which are several centimeters long, convert to vellus follicles that produce small hairs that protrude only slightly from the skin surface. Later in life, vellus follicles on the male beard enlarge into terminal follicles that generate thick, long hairs. On the scalp of genetically predisposed individuals, terminal follicles miniaturize and form effete, microscopic hairs.

Epithelial Placode or Primary Hair Germ

In the human fetus, hair follicles develop from small collections of cells, called *epithelial placodes,* which correspond to stage 1 of hair follicle development and first appear around 10 weeks' gestation (see Fig. 84-1). The epithelial placode then expands to form the "primary hair germ" whose progeny eventually generate the entire epithelial portion of the hair follicle.[23]

The cells of the hair placode and germ express placental cadherin and become oriented vertically, losing their desmosomes, hemidesmosomes, and epithelial cadherin, which decreases their adhesion to their neighbors.[24–26] Dermal cells beneath the hair placode form a cluster (or condensate), which later develops into the dermal papilla.[27]

Hair follicle formation depends on a series of mesenchymal/epithelial interactions.[27] An initial signal arises in the mesenchyme (primitive dermis) and instructs the overlying epithelium to form an appendage, indicated by the appearance of regularly spaced placodes (see Fig. 84-1). The second signal arises from the epithelial placode and causes an aggregation of cells in the underlying mesenchyme that will eventually form the dermal papilla. Finally, a signal from this primitive dermal papilla initiates prolif-

eration and differentiation of placode cells, ultimately leading to formation of a mature follicle. These reciprocal signals pass through the intervening basement membrane, which undergoes alterations in its morphology and chemical composition that may alter its ability to sequester growth factors and binding proteins, thus possibly modulating the epithelial/mesenchymal interactions.

Many of these regulatory molecules important for the formation of the hair follicle have been defined, but how they interact to generate hair follicles in an otherwise homogeneous epithelium has yet to be determined. In one model, the spacing and size of placodes are regulated by a dermal signal, which varies in character in different body regions. The dermal signal occurs uniformly within each body region and triggers the activation of promoters and repressors of follicle fate in the epithelium that then compete with one another, resulting in the establishment of a regular array of follicles.[15,28] Differences in the levels of promoter and repressor activation could account for regional differences in the size and spacing of follicles. Consistent with this model, several positive and negative regulators of hair follicle fate are initially expressed uniformly in the epidermis and subsequently become localized to placodes.

One of the earliest molecular pathways that positively regulates hair follicle initiation is the WNT/β-catenin pathway. β-Catenin is the downstream mediator of WNT signaling. WNT proteins bind to receptors on the cell membrane and, through a series of signals, inhibit the degradation of cytoplasmic β-catenin. β-Catenin then translocates to the nucleus, forming a complex with the LEF/TCF family of transcription factors and resulting in expression of downstream genes.[15,28] Activation of this β-catenin pathway appears necessary for establishing epithelial competence—a state in which the epithelial tissue has the potential to form a hair follicle. Normally, the β-catenin pathway is inactive in the adult epidermis, but by artificially activating β-catenin in epidermal basal cells of adult transgenic mice, hair follicles develop de novo.[29] This remarkable finding could eventually have therapeutic implications, although constant activation of this pathway in the hair follicle also results in pilomatricomas and trichofolliculomas, two types of relatively rare cutaneous tumors.[29,30]

Ectodysplasin (*EDA*), a molecule related to tumor necrosis factor, and its receptor (*EDAR*) also are part of another major pathway that stimulates early follicle development in both mice and humans.[31] *EDA* gene mutations cause X-linked anhidrotic ectodermal dysplasia, a syndrome associated with decreased numbers of hair follicles, and defects of the teeth and sweat glands (see Chap. 143).[32] The *EDAR* gene is mutated in autosomal recessive and dominant hypohidrotic ectodermal dysplasias, causing identical phenotypes to those resulting from *EDA* mutations. The mouse *Edar* gene is expressed ubiquitously in the epithelium before placode formation, and then becomes restricted to placodes, whereas the *Eda* gene is ubiquitously expressed even after placode formation.[33] Mice with mutations in these genes have the same phenotype as humans with similar mutations, and mice overexpressing Eda in the epidermis show formation of the "fused" follicles due to the loss of proper spacing between neighboring hair placodes.[34,35]

In contrast to EDA and EDAR, which promote hair follicle development, members of the BMP family inhibit follicle formation. *Bmp2* is expressed diffusely in the ectoderm, but then localizes to the early placode and underlying mesenchyme, while *Bmp4* is expressed in the early dermal condensate.[36,37] BMP signaling inhibits placode formation, whereas neutralization of BMP activity by its antagonist Noggin promotes placode fate, at least in part via positive regulation of lymphoid enhancer factor 1 (Lef-1) expression.[36,38–40] Mice lacking Noggin have fewer hair follicles than normal and retarded follicular development.[40] The Notch pathway also appears to play a role in determining the follicular pattern. The Notch ligand Δ-1 is normally expressed in the mesenchyme underlying the placode[41–43] and, when mis-expressed in a small part of the epithelium, promotes and accelerates placode formation while suppressing placode formation in surrounding cells.[41,44]

Another secreted protein present in the follicular placode that plays a major role in epithelial-mesenchymal signaling is sonic hedgehog (Shh).[45,46] Skin from mice lacking Shh have extremely effete hair follicles with poorly developed dermal papillae.[47–49] Patched1 (Ptc1), the receptor for Shh, is expressed in the germ cells and the underlying dermal papilla, suggesting that Shh may have both autocrine and paracrine inductive properties necessary for hair germ and dermal papilla formation.[50] Patched is the gene deficient in basal cell nevus syndrome (see Chap. 116).[19]

The Bulbous Peg or Hair Bud

In the next stage of development, the bulbous peg or hair bud (or stage 2 of hair follicle development, see Fig. 84-1) is formed by elongation of the hair germ into a cord of epithelial cells. The mesenchymal cells at the sides of the peg will develop into the fibrous sheath of the hair follicle, and those at the tip of the peg will develop into the dermal papilla. The deepest portion of the follicle peg forms a bulbous structure that surrounds the underlying mesenchymal cells destined to become the dermal papilla. These epithelial cells will become the matrix of the hair follicle, which gives rise to the hair shaft and inner root sheath. The outer root sheath forms two bulges on the side of the hair follicle forming an obtuse angle with the surface of the skin. The superficial bulge will develop into the sebaceous gland. The deeper bulge serves as the future site of epithelial stem cells that generate the new lower follicle during hair follicle cycling. The arrector pili muscle usually attaches in the bulge area, and contraction of the muscle causes a more vertical orientation of the hair shaft leading to "goose bumps." In the axillae, anogenital region, areolae, periumbilical region, eyelids (the specialized glands of Moll), and external ear canals, a third bulge develops superficial to the sebaceous gland bud and gives rise to the apocrine gland.

As the hair follicle bulb appears during the bulbous peg stage, at least eight different cell layers constituting all of the components of the mature hair follicle are formed. Understanding which genes determine specific cell lineages within the follicle is an important question. GATA-3 is important in inner root sheath differentiation.[51] Notch1, a membrane protein involved in determining cell fate through cell–cell interactions and intracellular signal transduction, and its ligands Serrate1 and Serrate2 are expressed in matrix cells destined to form the inner root sheath and hair shaft.[43,52] Notch1 appears to control the phenotype of keratinocytes as they leave the bulb matrix and differentiate into specific cell types.[53]

Mature Hair Follicle

The central lumen where the hair shaft will emerge is formed by necrosis and

cornification of epithelial cells in the infundibulum. As the hair shaft is produced, several signaling pathways are involved in the control of its differentiation. Wnt/β-catenin/Lef-1 signaling plays an important role in hair shaft formation, and ectopic expression of Wnt3 in the hair follicle outer root sheath causes hair shaft fragility.[54,55] Hair shaft keratin genes contain binding sites for Lef-1,[56] which translocates to the nucleus after activation of the WNT/β-catenin pathway. WNT signaling probably regulates expression of hair shaft keratin genes, because nearly all of these genes contain Lef-1 binding sites in their promoter regions.[57]

BMP signaling is also essential for proper differentiation of the inner root sheath and hair shaft, because conditional deletion of BMP receptor type 1A in keratinocytes results in profound alterations of the inner root sheath and hair shaft formation.[58–60] Several other putative transcription factors control hair shaft differentiation, including HOXC13,[6] a homeobox protein, and the WHN gene,[61–63] which is mutated in nude mice and rarely in humans with hair, nail, and immune defects.[64,65]

This process of hair follicle formation is repeated in several waves, with the formation of secondary follicles alongside the initial follicle. The follicles are primarily clustered into groups of three and possess an oblique orientation with a similar angle to their neighbors.

ANATOMY

Hair Types

After formation of the lanugo hair that is characteristic of the prenatal period, there are two major types of hair classified according to size (Table 84-1). Terminal hairs are typically greater than 60 ™m in diameter, possess a central medulla, and can grow to well over 100 cm in length. The duration of the growing stage (anagen) determines the length of the hair. The hair bulb of terminal hairs in anagen is located in the subcutaneous fat. In contrast, vellus hairs are typically less than 30 ™m in diameter, do not possess a medulla, and are less than 2 cm in length. The hair bulb of vellus hairs in anagen is located in the reticular dermis. Terminal hairs are found on the scalp, eyebrows, and eyelashes at birth. Vellus hairs are found elsewhere, and, at puberty, vellus hair follicles in the genitalia, axillae, trunk, and beard area in men transform into terminal hair follicles under the influence of sex hormones. Terminal hair follicles in the scalp convert to vellus-like or miniaturized hair follicles during androgenetic alopecia (see Chap. 86).[1,66]

TABLE 84-1
Hair Types and Characteristics

TYPE OF HAIR	ANAGEN DURATION	SIZE (DIAMETER, LENGTH)
Lanugo	1–3 mo	40 ™m, 1–2 cm
Vellus	1–2 wk	< 30 ™m, < 2 cm
Terminal	> 1 y	> 60 ™m, 10– > 100 cm
Miniaturized	< 1 wk	< 30 ™m, < 2 cm

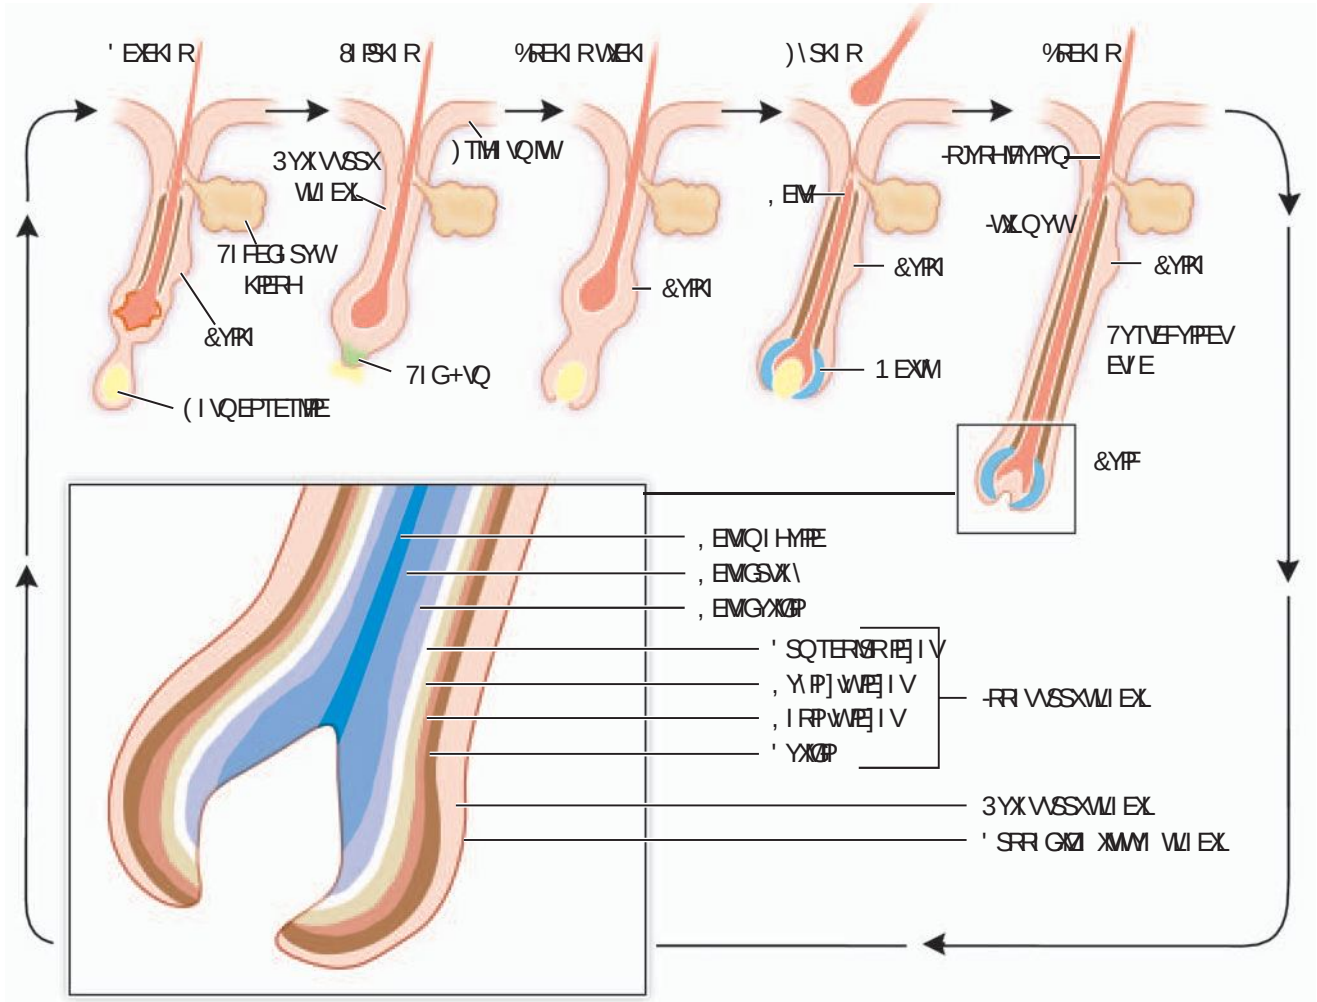
The curvature of the hair varies greatly among different individuals and races, and ranges from straight to tightly curled. Curved hair shafts arise from curved hair follicles. The shape of the inner root sheath is thought to determine the shape of the hair. Curled hair in cross-section is more elliptical or flattened in comparison with straight hair, which is more round. Several genes influencing hair shape have been identified. Mutations in the epidermal growth factor receptor (EGFR) pathway and in insulin-like growth factor binding protein 5 result in curly hair in mice.[67,68]

Microscopic Anatomy

The upper follicle consists of the infundibulum and the isthmus, and the lower follicle consists of the suprabulbar and the bulbar areas (Fig. 84-2).[14,63] The upper follicle is permanent, but the lower follicle regenerates with each hair follicle cycle. The major compartments of the hair from outermost to innermost include the connective tissue sheath, the outer root sheath, the inner root sheath, the cuticle, the hair shaft cortex, and the hair shaft medulla, each characterized by distinct expression of the hair follicle–specific keratins (Table 84-2).[69,70]

OUTER ROOT SHEATH The outer root sheath is continuous with the epidermis (see Fig. 84-2) at the infundibulum and continues down to the bulb. The cells of the outer root sheath change considerably throughout the follicle. The outer root sheath in the infundibulum resembles epidermis and forms a granular layer during its keratinization. In the isthmus, the outer root sheath cells keratinize in a trichilemmal fashion, lacking a granular layer. Trichilemmal keratinization occurs where the inner root sheath begins to slough. Desmoglein expression markedly changes here as well and trichilemmal or pilar cysts retain these characteristics.[71] Keratinocytes in the outer root sheath form the bulge at the base of the isthmus (see Hair Follicle Stem Cells). These cells generally possess a higher nuclear to cytoplasmic ratio compared with other areas of the follicle. Moving downward, the outer root sheath cells become much larger and contain abundant glycogen in the suprabulbar follicle. In the bulb, the outer root sheath consists of only a single, flattened cell layer that can be traced to the base of the follicle.

INNER ROOT SHEATH The inner root sheath extends from the base of the bulb to the isthmus and contains four parts from outermost to innermost: companion layer, Henle's layer, Huxley's layer, and the inner root sheath cuticle. The companion layer (see Fig. 84-2) has been referred to as the innermost layer of the outer root sheath, but recent evidence indicates that it is more like inner root sheath than outer root sheath.[72] The companion layer attaches to Henle's layer and moves upward with the rest of the inner root sheath; thus, it provides a slippage plane between the outer root sheath, which is stationary, and the inner root sheath.[75] The companion layer is prominent in some follicles (e.g., the beard) compared with others. The cells of the companion layer are flat compared to the cuboidal outer root sheath cells and express a type II cytokeratin, K6hf.[72] Henle's layer is one-cell-layer thick and is the first to develop keratohyaline granules and the first to keratinize. Huxley's layer is two to four cell layers thick and keratinizes above Henle's layer at the region known as *Adamson's fringe*. Some cells within Huxley's layer protrude through Henle's layer and attach directly to the companion layer. These cells are called *Fluegelzellen* or *wing cells*.[73] The cells of the inner root sheath cuticle partially overlap, forming a "shingled roof" appearance, and they intertwine precisely with the cuticle cells of the hair shaft. This association between the two cuticles anchors the hair shaft tightly to the follicle. The inner root sheath, composed of hard keratins and associated proteins (see Table 84-2), is thought to



▲ **FIGURE 84-2** Hair cycle and anatomy. The hair follicle cycle consists of stages of rest (telogen), hair growth (anagen), follicle regression (catagen), and hair shedding (exogen). The entire lower epithelial structure is formed during anagen and regresses during catagen. The transient portion of the follicle consists of matrix cells in the bulb that generate seven different cell lineages, three in the hair shaft and four in the inner root sheath. B = bulge; E = epidermis; DP = dermal papilla; H = hair shaft; M = matrix; ORS = outer root sheath; S = sebaceous gland; Sec Grm = secondary germ.

TABLE 84-2
Expression of Keratin Genes in Distinct Hair Follicle (HF) Compartments

HF Compartments	Type I Keratins, New Nomenclature (Old Nomenclature)	Type II Keratins, New Nomenclature (Old Nomenclature)

[a]Autosomal dominant mutations of K81 and K86 lead to monilethrix (alopecia due to increased hair fragility).

From Langbein L et al: K25 (k25irs1), K26 (k25irs2), k27 (k25irs3), and k28 (k25irs4) represent the type I inner root sheath keratins of the human hair follicle. . -RZ1 VW(I VQEXSP**26**:2377, 2006; and Langbein L, Schweizer J: Keratins of the human hair follicle. -RX6I Z'] XS**P243**:1, 2005, with permission.

dictate hair shape by funneling the hair shaft cells as they are produced. The transcription factor, GATA-3, is critical for inner root sheath differentiation and lineage. Mice lacking this gene fail to form an inner root sheath.[51]

HAIR SHAFT The hair shaft (and inner root sheath) arises from rapidly proliferating matrix keratinocytes in the bulb, which have one of the highest rates of proliferation in the body. The cells of the future hair shaft are positioned at the apex of the dermal papilla and will form the medulla, cortex, and hair shaft cuticle (see Fig. 84-2). Immediately above the matrix cells, hair shaft cells begin to express specific hair shaft keratins in the prekeratogenous zone. The differentiation of hair shaft cells in this zone is dependent on the Lef-1 transcription factor. Lef-1 binding sites are present in most hair keratin genes. BMP receptor type 1a is also critical for matrix cell differentiation into the hair shaft, because loss of this receptor prevents hair shaft differentiation.[58–60]

The hair shaft cuticle covers the hair, and its integrity and properties greatly impact the appearance of the hair. Once the hair exits the scalp, the cuticle endures weathering, and it is often completely lost at the distal ends of long hairs. Inside the cuticle, the cortex comprises the bulk of the shaft and contains melanin. The cortex is arranged in large cable-like structures called *macrofibrils*. These, in turn, possess microfibrils that are composed of intermediate filaments. The medulla sits at the center of larger hairs, and specific keratins expressed in this layer of cells (see Table 84-2) are under the control of androgens.[74]

DERMAL PAPILLA The dermal papilla (see Fig. 84-1) is a core of mesenchymally derived tissue enveloped by the matrix epithelium. It is comprised of fibroblasts, collagen bundles, a mucopolysaccharide-rich stroma, nerve fibers, and a single capillary loop. It is continuous with the perifollicular sheath (dermal sheath) of connective tissue that envelops the lower follicle.

Tissue recombination experiments have shown that the dermal papilla has powerful inductive properties, including the ability to induce hair follicle formation when transplanted below non–hair-bearing footpad epidermis.[75,76] This shows that the tissue patterning established during the fetal period can be altered under appropriate conditions. In human follicle, the volume of the dermal papilla correlates with the number of matrix cells and the resulting size of the hair shaft.[77] In mice, sizes of the hair bulb and hair diameter strongly depend of the proliferative activity of the matrix keratinocytes.[78]

Many soluble growth factors originate from the dermal papilla that appear to act in a paracrine manner on the overlying epithelial matrix cells. Specifically, keratinocyte growth factor (KGF) is produced by the anagen dermal papilla, and its receptor, fibroblast growth factor receptor 2 (FGFR2), is found predominantly in the matrix keratinocytes. Injections of KGF into nude mice produce striking hair growth at the site of injection,[79] suggesting that KGF is perhaps necessary for hair growth and cycling. Surprisingly, however, KGF knockout mice develop morphologically normal hair follicles that produce "rough" or "greasy" hair; thus KGF's effects on hair follicle morphogenesis and cycling appear dispensable or replaceable by other growth factors with redundant functions.[80]

HAIR FOLLICLE INNERVATION Myelinated sensory nerve fibers run parallel to hair follicles, surrounding them and forming a network (reviewed in ref. 81). Smaller nerve fibers form an outer circular layer, which is concentrated around the bulge of terminal follicles and the bulb of vellus follicles. Several different types of nerve endings, including free nerve endings, lanceolate nerve endings, Merkel cells, and pilo-Ruffini corpuscles are found around hair follicles.[82] Each nerve ending detects different forces and stimuli. Free nerve endings transmit pain, lanceolate nerve endings detect acceleration, Merkel cells sense pressure, and pilo-Ruffini structures detect tension. Perifollicular nerves contain neuromediators and neuropeptides, such as substance P or calcitonin gene–related peptide, that influence follicular keratinocytes and alter hair follicle cycling.[83–87] Conversely, hair follicle keratinocytes produce neurotrophic factors that influence perifollicular nerves and stimulate their remodeling in hair cycle-dependent manner.[87,88] Merkel cells that are considered neuroendocrine cells also produce neurotrophic factors, cytokines, or other regulatory molecules. Because Merkel cells are concentrated in the bulge area, some have postulated that these secreted factors may influence the cycling of the hair follicle.[89]

PERIFOLLICULAR SHEATH The perifollicular sheath envelops the epithelial components of the hair follicle and consists of an inner basement membrane called the *hyaline* or *vitreous (glassy) membrane* and an outer connective tissue sheath. The basement membrane of the follicle is continuous with the interfollicular basement membrane. It is most prominent around the outer root sheath at the bulb in anagen hairs. During catagen, the basement membrane thickens and then disintegrates.

Surrounding the basement membrane is a connective tissue sheath comprised primarily of type III collagen. Around the upper follicle, there is a thin connective tissue sheath continuous with the surrounding papillary dermis and arranged longitudinally. Around the lower follicle, the connective tissue sheath is more prominent, with an inner layer of collagen fibers that encircle the follicle surrounded by a layer of longitudinally arranged collagen fibers.[63]

When transplanted under the skin, this perifollicular connective tissue has the remarkable ability to form a new dermal papilla and induce new hair follicle formation.[90] Even when the connective tissue sheath is transplanted to another individual, these follicles survive without evidence of immunologic rejection.

HAIR FOLLICLE CYCLE

Each individual hair follicle perpetually traverses through three stages: growth (anagen), involution (catagen), and rest (telogen).[12] The length of anagen determines the final length of the hair and thus varies according to body site; catagen and telogen duration vary to a lesser extent depending on site. Scalp hair has the longest anagen of 2 years to more than 8 years. Anagen duration in young males at other sites is shorter: legs, 5 to 7 months; arms, 1.5 to 3.0 months; eyelashes, 1 to 6 months; and fingers, 1 to 3 months. In contrast to most mammals, including mice and newborn humans, in the adult human the hairs of the scalp grow asynchronously. Approximately 90 percent to 93 percent of scalp follicles are in anagen and the rest primarily in telogen.[91] Applying these figures to the 100,000 to 150,000 hairs on the scalp indicates that approximately 10,000 scalp hairs are in telogen at any given time. However, because we lose only 50 to 100 hairs per day, this indicates that telogen is a heterogenous state. The follicles that are shedding their hair shaft are thus in "exogen," which comprises approximately 1 percent of the telogen hair follicles

(see Fig. 84-2). Hair on the scalp grows at a rate of 0.37 to 0.44 mm/day or approximately 1 cm/month.

Hair Follicle Stem Cells

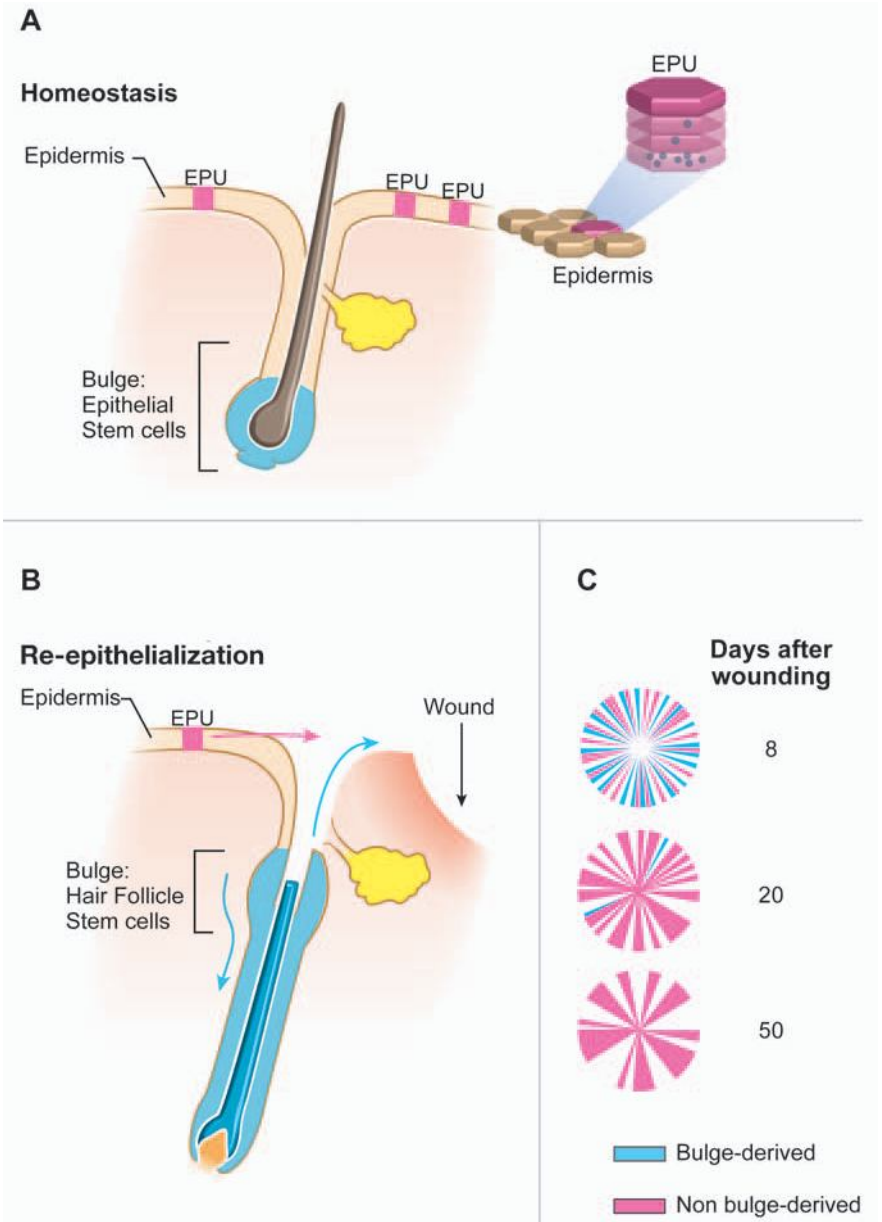
Because the lower portion of the follicle cyclically regenerates, hair follicle stem cells were thought to govern this growth. Historically, hair follicle stem cells were assumed to reside exclusively in the "secondary germ" (see Fig. 84-2), which is located at the base of the telogen hair follicle. It was thought that the secondary germ moved downward to the hair bulb during anagen and provided new cells for production of the hair. At the end of anagen, the secondary germ was thought to move upward with the dermal papilla during catagen to come to rest at the base of the telogen follicle. This scenario of stem cell movement during follicle cycling was brought into question when a population of long-lived presumptive stem cells was identified in an area of the follicle surrounding the telogen club hair.[92] Subsequently, it was shown that the secondary germ is a transient structure that forms at the end of catagen from cells in the lower bulge.[93] The concept that hair follicle stem cells are permanently located in the bulge has now been confirmed using lineage analysis, which showed that the bulge cells give rise to all epithelial layers of the hair follicle.[11,94,95] In line with this, ablation of bulge cells results in destruction of the follicle.[93] These findings support the notion that loss of hair follicle stem cells in the bulge leads to permanent or cicatricial types of alopecia.

Are bulge cells the "ultimate" stem cells within the skin epithelium? For example, do they generate epidermis and sebaceous glands during homeostasis and after wounding? To answer these questions, lineage analysis and transgenic techniques were again used. As illustrated in Fig. 84-3, bulge cells do not normally move to the epidermis, but after full-thickness excision of the skin, bulge cell progeny migrate into the wound during reepithelialization.[11,93] These cells comprise approximately 30 percent of the cells in the regenerated epidermis. The role of bulge cells in sebaceous gland maintenance is still not clear, but is under investigation.

Anagen

The formation of a new lower follicle and hair at anagen onset recapitulates folliculogenesis in the fetus. Anagen can be divided into seven stages: stage I—growth of the dermal papilla and onset of mitotic activity in the germ-like overlying epithelium; stage II—bulb matrix cells envelop the dermal papilla and begin differentiation, evolving bulb begins descent along the fibrous streamer; stage III—bulb matrix cells show differentiation into all follicular components; stage IV—matrix melanocytes reactivate; stage V—hair shaft emerges and dislodges telogen hair; stage VI—new hair shaft emerges from skin surface; and stage VI—stable growth.[96]

During proliferation and migration of keratinocytes into the dermis to reform the new lower follicle, enzymes such as proteases and collagenases appear at the leading edge of the downgrowth, and growth factors and their receptors are upregulated similar to an epithelial wound.[12] Pathways of keratinocyte differentiation that are seen in the epider-



▲ **FIGURE 84-3** Relationship between epidermal and hair follicle stem cells during homeostasis and after wounding. **A.** During normal conditions, epidermal renewal is dependent on cell proliferation within epidermal proliferative units (EPUs), which are clonal populations of cells roughly arranged in hexagonally shaped columns that produce a single outer squame. Epithelial stem cells in the hair follicle bulge do not contribute to epidermal renewal. **B.** After full-thickness wounding, bulge cells contribute cells to the epidermis for immediate wound closure (FPPL YT[EVHEXS[). Bulge cells also are required for hair follicle cycling (FPPL HS[R[EVHEXS[) **C.** Over time, bulge-derived cells diminish, whereas non-bulge–derived cells (from the interfollicular epidermis and infundibulum) appear to predominate in the re-epithelialized wound.

mis during wound healing, such as expression of keratin 6, are activated. Mice lacking Stat3, a regulator of cell migration in the cutaneous epithelium, show defects in wound healing and a failure of hair follicles to enter anagen,[97] thus further illustrating the similarity between wound healing and the early events of anagen. Remarkably, the dermal papilla in the midst of this degradative milieu survives and moves downward. Neurocutaneous and vascular networks are remodeled.[88,92] Melanocytes proliferate and repopulate the new hair bulb.[98] Finally, a burst of endothelial proliferation and angiogenesis in the dermal papilla marks the time point when the lower follicle is completely restored and is actively producing the new hair shaft.[99]

Catagen

The onset of catagen is marked by cessation of the mitotic activity of the matrix cells and by well-coordinated apoptosis in the cyclic portion of the hair follicle (reviewed in refs. 12 and 100). Pigment production by melanocytes ceases before matrix cell proliferation stops, thus leading to a non-pigmented proximal end in the telogen club hair (see Fig. 84-2). Melanin is often found in the surrounding dermis and papilla where it is engulfed by macrophages. The perifollicular sheath collapses, and the vitreous or glassy membrane thickens. The lower follicle retracts upward with the dermal papilla. The perifollicular sheath forms a fibrous streamer comprised of fibroblasts, small blood vessels, and collagen.[1] Eventually, the dermal papilla becomes situated immediately below the bulge at the lower portion of the isthmus.

During catagen, the largest follicles, on the scalp for example, shorten their length from 2- to 5-mm-long structures whose deepest portion, the bulb, extends down into the subcutaneous fat to truncated 0.25- to 0.5-mm follicles in telogen. As the basement membrane around the lower follicle thickens, the dermal papilla, protected from the surrounding apoptosis and destruction (perhaps because it expresses Bcl-2, an anti-apoptotic factor[12]) condenses and begins to move upward to come to rest below the bulge during telogen. The migration of the dermal papilla from the subcutaneous fat to the dermis during catagen is necessary for continued follicle cycling. This is illustrated by the syndrome of atrichia with papules.[101,102] These patients have mutations in either their hairless gene or in their vitamin D receptor gene, in which case they also have rickets. Mice with similar mutations have the hairless phenotype. We know from these mice that folliculogenesis is normal; however, when the follicles enter catagen for the first time, the lower portion of the follicle does not involute and contract properly, and the dermal papilla remains stranded in the subcutaneous fat.[92] Although bulge cells are still present, no new anagen follicles ever form, presumably because the stem cells cannot interact with the dermal papilla.[92]

The study of mouse mutants has also resulted in several key findings that have increased our understanding of the molecular events at catagen onset. Specifically, Hebert et al.[3] discovered that mice lacking the *Fgf5* gene have hair that is 50 percent longer than their wild-type litter mates, and that mutations in this gene are responsible for the angora phenotype that was described more than 30 years ago. Although these findings were rather unexpected, careful evaluation of *Fgf5* expression throughout the normal hair cycle demonstrated that its expression was upregulated in the outer root sheath and hair matrix cells just before the onset of catagen, suggesting that *Fgf5* may trigger catagen onset. Interestingly, the follicle still eventually entered catagen, even in the absence of FGF-5, suggesting redundancy in the FGF-5 pathway or an intrinsic finite proliferative capability of the matrix cells.[92] Further studies also demonstrated that other FGF family members and their receptors are expressed during anagen, and probably also play a role in the hair follicle cycle.[103] The hair phenotype of FGF-5–deficient mice is substantially reversed by ectopic expression of the anti-apoptotic gene *bcl-xL*$_x$ in the outer root sheath, suggesting that regulation of cell survival in the outer root sheath may play a role in control of the hair growth cycle.[104]

Although it has been known for many years that exogenous EGF administered to sheep results in catagen induction,[105] only through more recent transgenic and knockout studies in mice has the importance of the EGFR system in hair cycle regulation been realized.[67,106] For example, knockout mice lacking transforming growth factor-α (TGF-α), the major ligand for EGFR, have abnormal hair follicle development and manifest the waved hair phenotype.[4,5] When EGFR is functionally downregulated in the basal layer of the epidermis and hair follicle using a dominant negative transgenic strategy, the resulting hair is not only waved, but also longer than normal.[67] The transition of the hair follicles from anagen to catagen is delayed in these mice. Hair follicles in mouse skin that completely lack EGFR also do not progress from anagen to telogen.[106] Thus, EGFR and its ligand are required for normal hair follicle development and cycling. Given the complexity of the EGFR family, which includes four receptors (ErbB1–4) and at least six ligands, future studies are needed to clarify the role of individual family members in hair follicle cycling.[107]

In addition to FGF-5 and EGF, neurotrophins and TGF-β1 induce premature catagen. Neurotrophin-3 and brain-derived neurotrophic factor transgenic mice show premature catagen development, and brain-derived neurotrophic factor overexpression leads to the shortening of hair length by 15 percent, most likely via stimulation of pro-apoptotic signaling through p75 kd neurotrophin receptor.[108,109] TGF-β1 induces premature catagen in isolated human hair follicles and in mouse skin in vivo, and TGF-β1 knockout mice display delay in catagen onset.[110–112]

Telogen and Exogen

Once the involution of catagen is complete and a club hair is formed (see Fig. 84-2), the hair follicle prepares the hair for expulsion from the scalp. About 1 percent of telogen follicles are shed each day. Milner et al.[113] have proposed distinguishing hair shedding as a separate phase called *exogen*. Exogen is a highly controlled and timed event in mammals that shed on a seasonal basis. That exogen is an active stage is supported by Headington's description of one type of telogen effluvium he termed *immediate telogen release*.[114] This type of hair loss can be seen soon after starting medications, such as minoxidil, or in response to rapid fluctuations in light/dark cycles. It consists of an increase in shedding of club hairs within weeks of the precipitating event (too soon to be caused by follicles prematurely entering telogen from anagen), suggesting that club hairs that are normally retained in the follicle can be actively shed. The heterogeneity of telogen is further supported by the work of Guarrera and Rebora,[115] who followed individual hairs in situ using macrophotographs for more than 2 years and showed that several months could transpire between hair shedding and regrowth. This "lag period" is nor-

mally not present or is very short, but often lasts several months in patients with androgenetic alopecia.

HAIR PIGMENTATION

Hair becomes pigmented as a result of a tightly coordinated program of melanin synthesis and transport from the hair bulb melanocytes to differentiating hair shaft keratinocytes.[116–118] This process is strictly coupled to anagen and ceases during catagen and telogen. Numerous signaling molecules, structural proteins, enzymes, co-factors, and transcriptional regulators control hair pigmentation (Figs. 84-4 and 84-5).[116,118,119]

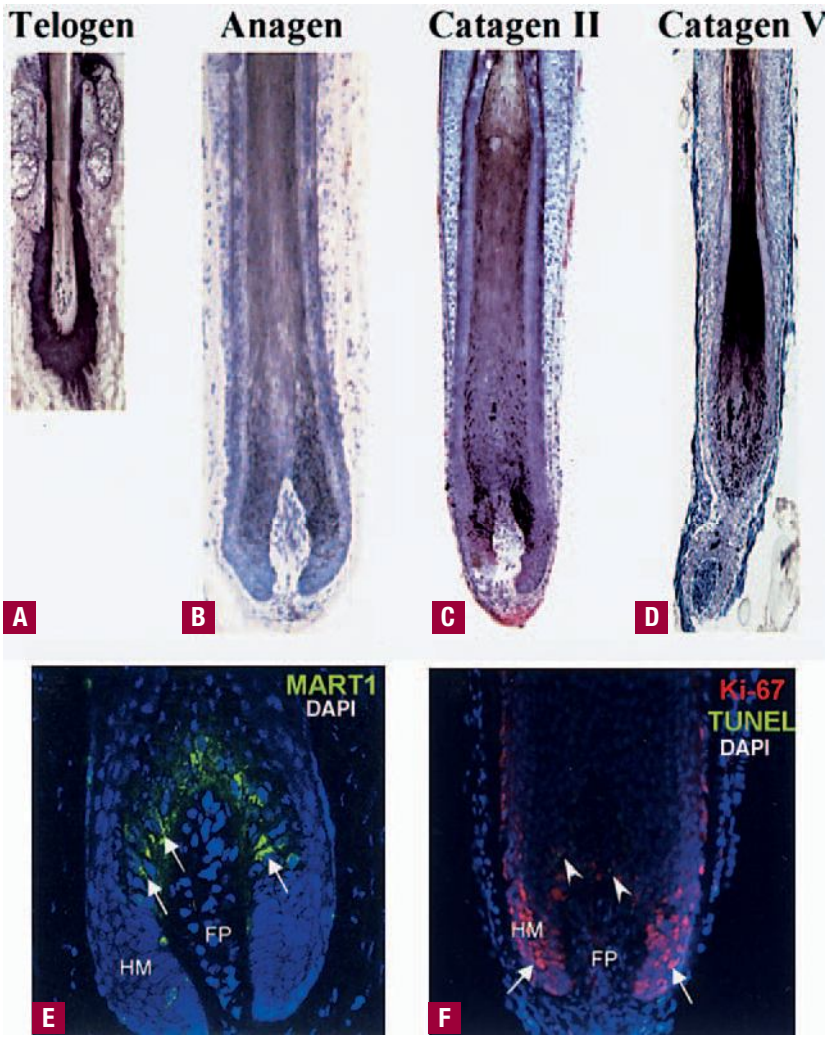
Hair Melanocyte Development

Melanoblasts can be identified in the epidermis of human embryos at 50 days of estimated gestational age before the onset of hair follicle morphogenesis.[120–122] These follicular melanocytes originate in the neural crest and migrate first to the dermis and then epidermis.[123] Commitment of neural crest cells to the melanocyte lineage is regulated by Pax3 and microphthalmia transcription factors (Mitf), which stimulate the expression of dopachrome tautomerase [or tyrosinase-related protein 2 (Trp2)], an enzyme involved in melanin biosynthesis that also functions as an early melanoblast marker.[122] Subsequent steps of melanoblast development (migration into the dermis and epidermis) are controlled by signaling mechanisms activated through endothelin receptor type B and c-kit oncogene (c-kit) receptor, which are mutated in humans with Hirschprung disease and piebaldism, respectively, resulting in formation of unpigmented hairs.[123]

After entering the placode of the developing hair follicle, melanoblasts proliferate and become melanogenically active synchronously with the onset of hair fiber formation.[124] Experimental and genetic data suggest that migration of melanoblasts into the hair follicle and their development toward melanogenically active forms depend on stem cell factor (SCF)/c-kit signaling. SCF is a ligand that binds to its receptor, c-kit. Pharmacologic blockade of c-kit during embryogenesis, as well as genetic ablation of SCF or c-kit in corresponding mouse mutants results in unpigmented hairs.[125–127]

Hair Follicle Melanocyte Stem Cells and Pigment-Producing Melanocytes

MSCs located in the hair follicle bulge generate progeny that repopulate the melanocytes in the new hair bulb formed at the onset of anagen.[97,128] MSCs express Trp2, Bcl-2, Pax3, while other melanogenic enzymes (tyrosinase, Trp1) and signaling molecules (c-kit, endothelin receptor type B, SOX10, Mitf and Lef-1)[129] are expressed at low levels. MSCs can be first detected in the bulge area during late stages of hair follicle morphogenesis and similarly to epithelial stem cells they show bromodeoxyuridine-retaining capacity.[128–130] Bcl-2 plays a key role in maintenance of MSCs, and Bcl-2 knockout mice show progressive hair graying due to the depletion of MSCs.[129–132] However, Bcl-2 deficiency may be compensated by overexpression of SCF, which rescues loss of MSCs in the hair follicle bulge of Bcl-2 knockout mice.[129]

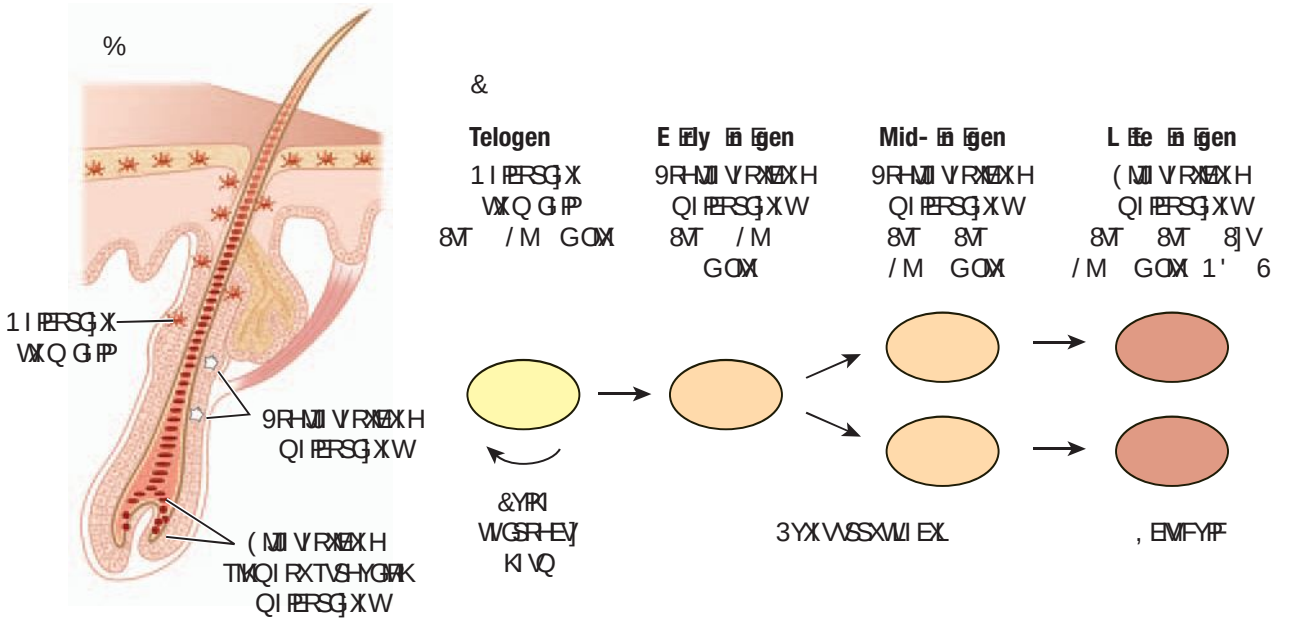


▲ **FIGURE 84-4** Morphology and fluorescent microscopy of human hair follicle at distinct hair cycle stages. **A–D**. Morphology of human hair follicle during telogen (**A**), late anagen (**B**), and early and late catagen (**C**, **D**). **E.** Immunofluorescent visualization of the melanocytes (EWS[YWin the hair bulb of late anagen hair follicle with anti–melanoma-associated antigen recognized by T cells antibody. **F.** Immunofluorescent detection of proliferative marker Ki-67 (EWS[YWand apoptotic TUNEL+ cells (EWS[LI EHYWin early catagen hair follicle. FP = follicular papilla; HM = hair matrix.

Melanogenically active melanocytes are located in the hair bulb above the dermal papilla.[98,118] These cells synthesize and transport melanin to hair shaft keratinocytes and express a full set of enzymes and other proteins involved in melanin biosynthesis including tyrosinase, Trp1, Trp2 (in mice), and pMel17 (in humans).[99,129]

Hair Cycle–Dependent Changes in Melanocytes

Hair follicle melanocytes undergo substantial remodeling during hair follicle cycling.[98,118] In telogen, hair follicle melanocytes are found in the bulge, secondary hair germ, and connective tissue.[98] In humans, melanocytes in the telogen hair follicle do not express Trp1 or tyrosinase



▲ **FIGURE 84-5** Hair cycle–dependent remodeling of the follicular pigmentary unit. **A.** Scheme illustrating localization of distinct sub-populations of melanocytes in anagen hair follicle. **B.** Dynamics of the follicular melanocytes during anagen. Expression of melanogenic markers and growth factor receptors indicated is based on the data obtained from murine hair follicles. Note that human follicular melanocytes do not express tyrosinase-related protein 2 (Trp2). c-kit = c-kit oncogene. (From Ando H et al: Fatty acids regulate pigmentation via proteasomal degradation of tyrosinase: A new aspect of ubiquitin-proteasome function. . &MP LI Q**279**:15427, 2004, with permission.)

and do not proliferate. Melanocytes can be visualized by expression of pMel17.[133] Some of these cells also express c-kit receptor, whereas others remain c-kit-negative and represent MSCs.[98,128,129]

During early anagen, resting melanocytes proliferate, differentiate, and migrate within the hair follicle synchronously with regeneration of the hair follicle bulb. Hair follicle melanocytes are maximally proliferative during early and mid-anagen, and their transition to melanogenic competence is accompanied by the appearance of Trp1 and tyrosinase proteins.[98,134]

Similar to embryonic and early postnatal development, SCF/c-kit signaling plays a critical role in repopulation of the bulb with pigment-producing melanocytes. C-kit is expressed on proliferating, differentiating, and melanogenically active melanocytes, whereas overexpression of SCF in the epidermis of transgenic mice significantly increases the number of hair follicle melanocytes and their proliferative activity.[98] Similarly, administration of the ACK45 antibody blocking c-kit signaling dramatically reduces melanocyte number in anagen hair follicles, resulting in hair depigmentation.[98] However, in the next hair cycle, the previously treated animals grow fully pigmented hairs with the normal number and distribution of melanocytes, suggesting that MSCs are not dependent on SCF/c-kit.[98]

During catagen, melanogenic activity in the follicular melanocytes abruptly ceases. Immunohistochemical and electron microscopic data suggest that some pigment-producing melanocytes located above the follicular papilla undergo apoptosis, while others drop into the dermal papilla of the follicle.[135,136]

Molecular Control of Hair Color

Follicular melanocytes synthesize pigment via a cascade of enzymatic conversions of phenylalanine or tyrosine into brown-black eumelanin or yellow pheomelanin that requires melanogenic enzymes (tyrosinase, Trp1/2, γ-glutamyl transpeptidase, peroxidase) and essential co-factors, such as 6-tetrahydrobiopterin.[116,135] The balance between black and yellow pigment synthesis (eumelanin and pheomelanin, respectively) is regulated by signaling through the melanocortin type 1 receptor (MC-1R) that has long been implicated in the control of hair color.[137,138]

After binding to MC-1R, α melanocyte-stimulating hormone (α-MSH) stimulates adenylyl cyclase, resulting in elevation of intracellular cyclic adenosine monophosphate levels. This leads to increase of transcriptional activity of Mitf that stimulates synthesis of melanogenic enzymes (tyrosinase, Trp1/2) involved in eumelanin formation.[139,140] Pheomelanin synthesis in the hair follicle melanocytes of mice occurs when MC-1R signaling is inhibited by Agouti signal protein (ASP) that competes with α-MSH in binding to MC-1R.[138,139] In mice, ASP expression is positively regulated by BMP signaling, and transgenic mice overexpressing BMP antagonist Noggin show hair darkening.[141] Although ASP is expressed in human skin, its role in human pigmentation remains unclear.[140]

Recent data also demonstrate existence of fully functional proopiomelanocortin/MC-1R system in human hair follicles: MC-1R is expressed by hair follicle melanocytes, whereas its ligands α-MSH and adrenocorticotropic hormone are able to promote proliferation, dentricity, and melanogenesis.[142] Similar effects are seen with another proopiomelanocortin-derived peptide, β-endorphin that interacts with ™opiate receptor expressed by hair follicle melanocytes.[142] However, signaling through the ™opiate receptor may regulate hair pigmentation via modulating the activity of protein kinase C-β, a known positive regulator of melanogenesis.[143]

CONCLUSION

The hair follicle is formed as the result of a complex interplay of signals between epithelium and mesenchyme. The nature of these signals is just now being elucidated, with many molecular pathways important in development also playing roles in hair follicle formation. The product of this process is a miniature organ with distinctive vertical and concentric divisions. Both epithelial stem cells and MSCs in the follicle are important for the constant regeneration of the follicle.

CHAPTER 85

Keratosis Pilaris and Other Inflammatory Follicular Keratotic Syndromes

Maureen Rogers

Follicular keratosis refers to orthokeratosis involving the follicular ostium and infundibulum. Horny plugs protrude from the orifices, producing a rough sensation on palpation of the skin. It may be isolated [as in standard keratosis pilaris (KP)] or associated with other pathologic processes, including follicular inflammation, atrophy, scarring, and alopecia [keratosis pilaris atrophicans (KPA)]. These are reaction patterns that occur alone or as part of a wide variety of syndromes.

KERATOSIS PILARIS

Isolated typical KP is a common condition of keratotic follicular plugging with varying degrees of surrounding erythema. Sometimes, the erythema is so striking that it is the main complaint. The clinical expression of KP varies from very subtle to very conspicuous, which, along with possible racial differences, may explain the great range of reported prevalences, from 1 percent to 42 percent.[1–4] It involves, particularly, the extensor aspects of the upper arms (Fig. 85-1) and thighs as well as the face but may rarely be more extensive, extending to the distal limbs and even the trunk. There seem to be two patterns. The more common one is commencement in early childhood, in most cases before 2 years of age, with face and arms mainly affected and gradual improvement in most cases by later childhood or adolescence. In the other pattern, the onset is in teenage years, and the extensor arms and legs are predominantly involved. It usually improves by the mid-20s. In both patterns, however, the condition may be persistent into later adult life.[5] The histopathologic pattern in skin biopsy specimens is nonspecific, simply showing the follicular orifice distended by a keratin plug.

Treatment is usually with various keratolytics, from simple urea, lactic acid, or salicylic acid preparations to topical retinoids and tazarotene.[6] These preparations may aggravate associated erythema, limiting their value.

◀ **FIGURE 85-1** Keratosis pilaris in a characteristic distribution on upper outer arm in a patient with ichthyosis vulgaris.

KERATOSIS PILARIS AT A GLANCE

- Common condition of keratotic follicular plugging with variable erythema.
- Mainly involves cheeks and extensor arms and thighs.
- Two main patterns—early childhood onset and adolescent onset.
- Usually improves gradually over years.
- Non-specific histology of follicular orifice distended by keratin plug.
- Variable response to keratolytics.
- Erythromelanosis follicularis faciei et colli is a variant with marked erythema and hyperpigmentation.

Erythromelanosis Follicularis Faciei et Colli

Erythromelanosis follicularis faciei et colli is a condition probably related to KP.[7] It is seen primarily in adolescents and young adults, most commonly in males. Well-demarcated erythema, hyperpigmentation, and follicular papules involve the preauricular and maxillary areas, usually in a symmetric distribution, with spread in some cases to the temples and sides of the neck. Atrophy is not a feature. Histopathology is nonspecific, demonstrating a variable de-

KERATOSIS PILARIS ATROPHICANS AT A GLANCE

- A group of rare follicular keratosis conditions with follicular atrophy and/or alopecia
  - Ulerythema ophryogenes—keratosis pilaris atrophicans predominantly affects eyebrow area, causing scarring alopecia; occurs in various syndromes, including Noonan and cardiofaciocutaneous syndromes
  - Keratosis pilaris rubra atrophicans faciei—possibly a form of ulerythema ophryogenes; especially involves temples and cheeks
  - Atrophoderma vermiculatum—predominantly involves cheeks and leads to a striking honeycomb-like atrophy; mosaic forms described
  - Keratosis follicularis spinulosa decalvans—predominantly involves scalp, leading to severe cicatricial alopecia; associated features include plantar keratoderma and photophobia

gree of follicular hyperkeratosis, dilation of upper dermal vessels, some perivascular inflammatory infiltrate, and hyperpigmentation of the basal layer. The frequent association with standard KP of the arms suggests that the two conditions are related.

Associations of Keratosis Pilaris

Patients with ichthyosis vulgaris (see Chap. 47) often demonstrate KP; in one series KP was found in 74.3 percent of patients (see Fig. 85-1).[1] Contrary to conventional wisdom, however, the same series found that KP was not a feature in atopic dermatitis patients who lacked the ichthyosis vulgaris phenotype.[1] Other conditions in which KP is more prevalent or more prominent are hypothyroidism, Cushing syndrome, diabetes,[8] obesity, and Down syndrome. Follicular keratosis, which may simulate KP, can occur in several nutritional deficiencies, although vitamin A deficiency is most commonly cited (see Chap. 130).[9]

KERATOSIS PILARIS ATROPHICANS

The general term *keratosis pilaris atrophicans* is used to describe a group of rare genetic follicular keratosis conditions in which follicular atrophy and/or alopecia occur. These include ulerythema ophryogenes [UO or keratosis pilaris atrophicans faciei (KPAF)], atrophoderma vermiculatum, and keratosis follicularis spinulosa decalvans (KFSD). Although the conditions show overlapping clinical features and non-diagnostic histologic findings, most authors now regard the conditions as discrete entities.[10–12]

Ulerythema Ophryogenes

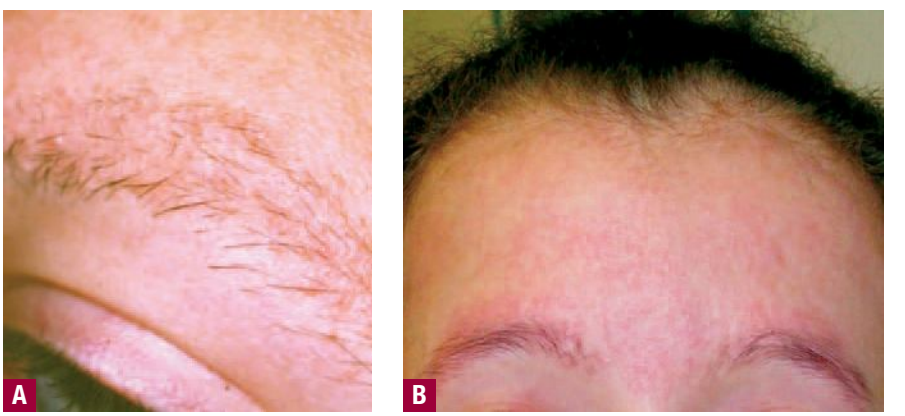
UO is a form of KPA affecting particularly and initially the eyebrow areas; in some cases extending later to the cheeks and forehead.[11] Scalp and eyelash hair is normal. The onset is within months of birth, with erythema and small keratotic follicular papules involving the lateral one-third of the eyebrows. It may slowly progress through childhood to involve more of the eyebrows and sometimes beyond, leading to alopecia (Fig. 85-2). Progression usually ceases after puberty but the sequelae are permanent. The condition is frequently associated with standard KP involving the arms and legs.

Most cases have followed an autosomal dominant inheritance pattern, with incomplete penetrance.[11] Response to topical corticosteroids, topical retinoids, and keratolytics has been poor. There is one report of a good response to several months' therapy with oral isotretinoin, with lessening of the horny plugs and the erythema.[13] The improvement was maintained for some months after therapy had ceased. Some improvement in erythema was reported with the pulsed tunable dye laser at 585 nm, but the follicular plugging was unchanged.[14]

KERATOSIS PILARIS RUBRA ATROPHICANS FACIEI Sometimes, keratosis pilaris rubra atrophicans faciei is used as a synonym for UO. At other times, it has been applied to a condition almost identical to UO that initially involves the temples or cheeks, rather than the eyebrows. Like characteristic UO, it begins in early childhood, is inflammatory, results in scarring, and is associated with typical KP of the limbs.[15]

ASSOCIATIONS OF ULERYTHEMA OPHYROGENES UO has been reported in association with isolated woolly hair,[16,17] Noonan syndrome,[16,18] cardiofaciocutaneous (CFC) syndrome,[19,20] Rubenstein-Taybi syndrome,[21] Cornelia de Lange syndrome,[22] 18p deletion,[23] and one case of multiple congenital abnormalities not typical of a recognized syndrome.[24] CFC syndrome and Noonan syndrome have overlapping clinical features, and, before understanding of the underlying molecular mechanisms, there was conjecture that CFC syndrome represented a severe variant of Noonan syndrome.[20] Mutations in genes of the Ras pathways have been demonstrated in patients with both diagnoses.[25,26] In CFC, mutations have been described in BRAF, KRAS, MEK1, and MEK2 genes.[26] Primarily PTPN11, but also KRAS and SOS1 genes, have been mutated in patients with Noonan syndrome.[27,28]

Follicular keratosis in Noonan syndrome, if present, is usually limited to the face (see Fig. 85-2B) and resembles UO/KPAF with loss of eyebrow hairs.[16,18] In CFC syndrome, follicular keratosis is often much more extensive, and there may



▲ **FIGURE 85-2** **A.** Ulerythema ophryogenes involving eyebrow area with scarring alopecia. **B.** Ulerythema ophryogenes involving the upper face in a patient with Noonan syndrome.

be striking alopecia involving the scalp.[20] The remaining scalp hair in CFC syndrome is brittle and curly. Patients with CFC syndrome may also show generalized thickening and psoriasiform scaling of the skin. Other cutaneous features that may be seen in Noonan syndrome are lymphedema, lymphatic malformations, prominent finger and toe pads, and pigmented nevi. The major non-cutaneous features of Noonan syndrome include short stature, hypertelorism, down-slanting palpebral fissures, low-set ears with thick helices, high nasal bridge, short webbed neck, sternal abnormalities, congenital heart defects (especially pulmonic valve anomalies), joint laxity, and hypotonia. The non-cutaneous features of CFC syndrome overlap to some extent and include short stature, macrocephaly, prominent forehead, short nose with a low nasal bridge, large posteriorly rotated ears, downward slanting palpebral fissures, cardiac malformations (especially pulmonic stenosis), and developmental delay.

Atrophoderma Vermiculatum (Folliculitis Ulerythematosa Reticulata)

Atrophoderma vermiculatum (folliculitis ulerythematosa reticulata) is a form of KPA in which the cheeks are predominantly involved, with follicular plugs and pit-like depressions up to 1.5 mm in diameter and a background of erythema. Alopecia and follicular papules are not features of the condition,[15,29] but sparse open and closed comedones and milia may be found.[30] The depressions merge into each other producing a "worm-eaten" or "honeycombed" appearance (Fig. 85-3). Involvement of the forehead, arm, and leg, as well as the typical cheek area, has been described.[31] In general, however, it is rare for the condition to involve the limbs, and eyebrow involvement does not occur. Standard KP of the extensor aspects of arms and legs is a common associated finding.[29] The onset is usually in childhood, between 5 and 12 years old, although later onset has been described; the course is usually one of inexorable worsening. The condition is often sporadic but, in some cases, appears to be inherited as an autosomal dominant trait.[32] Several more or less linear unilateral cases have been described,[33] suggesting a possible mosaic form of the condition.[34] However, it is possible that at least some of these cases may represent examples of nevus comedonicus.[34]

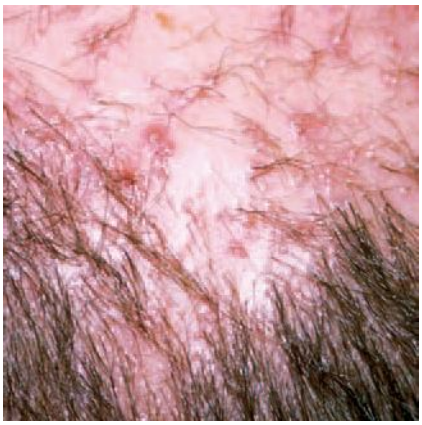
▲ **FIGURE 85-3** Atrophoderma vermiculatum demonstrating honeycomb atrophy on the cheek of an adolescent girl.

Histopathologic evaluation demonstrates atrophic pilosebaceous units with mild perifollicular and perivascular inflammation. The follicular orifices are dilated and filled with keratin plugs. Numerous dermal horn cysts may be found. There is perifollicular fibrosis and a decrease in elastic fibers in the dermis.[29,35]

Therapy is uniformly unsuccessful and has included topical steroids, topical retinoids, cryotherapy, and dermabrasion. There is a report of a partial response to chemical peeling with trichloroacetic acid 35 percent solution combined with topical application of 0.05 percent tretinoin cream.[36] Favorable results have also been described with carbon dioxide laser in a case in which atrophy was prominent, and pulsed dye laser in a case with a marked erythematous component.[30] Oral isotretinoin suppressed the inflammation in one patient.[37]

Keratosis Follicularis Spinulosa Decalvans

The term *keratosis follicularis spinulosa decalvans* was first used by Siemens in 1926 who described a scarring follicular condition in 20 members of a large family.[38] The condition begins in infancy with noninflammatory, flesh-colored, spiny lesions affecting hair-bearing areas, especially the scalp (Fig. 85-4) and later eyebrows, eyelashes, and the dorsal of the hands and fingers. Sometimes, more proximal limbs and even the trunk become involved.[38–40] An associated plantar keratoderma may occur, especially over the heels.[10] By puberty, many of the follicular spines have disappeared and are replaced by atrophy. Scarring alopecia of scalp (see Fig. 85-4), eyebrows, and eyelashes becomes apparent in childhood and progresses till puberty. It is often patchy and is rarely total. Facial lanugo hair is absent, and axillary and pubic hair are often thinned.



▲ **FIGURE 85-4** Keratosis follicularis spinulosa decalvans with severe scarring alopecia of scalp. (Photograph used with permission from Dr. Peter Hogan.)

Photophobia is seen in many patients, and punctate corneal epithelial defects have been seen in some.[39] It is unclear whether there is a primary epithelial defect or whether the corneal changes occur as a result of irritation from distorted remnant lashes and keratotic plugs in eyelash follicles. There are rare reports of other ophthalmologic abnormalities, including cataract and retinal detachment.[41]

Biopsy specimens show follicular-based hyperkeratosis, perifollicular and dermal inflammation, fibrosis, and distorted follicles at different stages of the condition. Family studies suggest an X-linked dominant inheritance pattern,[38,39,41,42] and the gene has now been localized to Xp22.13-p22.2.[43] In most series, men are more severely affected than women. As yet, no lesions have been described in a blaschkoid distribution in women to suggest random lyonization.

Eramo et al.[15] have pointed out the similarity of this condition to ichthyosis follicularis with alopecia and photophobia (IFAP) syndrome [see Ichthyosis Follicularis, Alopecia (Atrichia), and Photophobia Syndrome]. Features in KFSD not shared by IFAP, however, are involvement of the fingers, late atrophy and scarring of involved follicles, and the development in some patients of a red-brown telangiectatic pigmentation of cheeks and brows.

In general, treatment of KFSD is unsatisfactory; however, there are isolated reports of improvement in photophobia with oral vitamin A[39] and

remission of cutaneous inflammation and halting of the spread of alopecia with oral retinoids.[44]

Folliculitis Spinulosa Decalvans

A variant of KFSD has been called *folliculitis spinulosa decalvans* (acknowledging that this name may lead to confusion with the separate entity of folliculitis decalvans).[10] This variant is characterized by persistent pustule formation, especially on the scalp. Unlike the typical variant of KFSD, there is more severe inflammation, and it is ongoing rather than settling after puberty. In addition, the inheritance appears to be autosomal dominant rather than X-linked recessive.

OTHER SYNDROMES WITH FOLLICULAR KERATOSIS AS A SIGNIFICANT FEATURE

Apart from the conditions described in the preceding sections in association with UO, there are other conditions that have follicular keratosis as a significant feature (Table 85-1).

Monilethrix (See Chap. 86)

Monilethrix is an autosomal dominant condition producing a beaded appearance of the hair.[45] Recently, mutations in the human basic hair trichocyte keratins hHb1, hHb3, and hHb6 have been reported.[46–48] However, the failure to demonstrate these mutations in one family suggests the possibility of genetic heterogeneity.[49] A striking follicular keratosis is associated in some pedigrees and may involve the scalp (Fig. 85-5), face, and limbs. Genotype/phenotype correlation is not obvious in reported cases in which mutations have been identified.[50,51] A child of unaffected consanguineous parents has been described with severe monilethrix, widespread KP, cataracts, and facial dysmorphism with brachiocephaly.[52]

TABLE 85-1
Syndromes That May Feature Follicular Keratosis

- Monilethrix
- Keratosis pilaris and hereditary koilonychia
- Hereditary mucoepithelial dysplasia
- Ichthyosis follicularis, alopecia, and photophobia syndrome

- Cardiofaciocutaneous syndrome
- Noonan syndrome
- Rubenstein-Taybi syndrome
- Cornelia de Lange syndrome
- 18p deletion

▲ **FIGURE 85-5** Striking follicular keratosis of the scalp in a patient with monilethrix.

Keratosis Pilaris and Hereditary Koilonychia

A family has been described with koilonychia and widespread KP, involving all areas of trunk and limbs. Affected family members also showed eyebrow involvement with alopecia, simulating UO/KPAF.[53] The inheritance pattern appeared to be autosomal dominant. There was no monilethrix in these cases; previously KP and koilonychia have been reported together only in cases of monilethrix.

Keratitis, Ichthyosis, and Deafness Syndrome (See Chap. 47)

Widespread follicular keratosis is a striking feature of keratitis, ichthyosis, and deafness syndrome, a connexin/gap junction disorder, which is also characterized by alopecia of scalp, body, eyebrow, and eyelash hair, vascularizing keratitis, and a profound sensorineural hearing loss.[54]

Hereditary Mucoepithelial Dysplasia

The characteristic features of hereditary mucoepithelial dysplasia (HMD) are follicular keratosis, non-scarring alopecia with some coarse abnormal hairs remaining, fiery-red palatal and gingival mucosae, photophobia with demonstrable keratitis and corneal vascularization, and psoriasiform hyperkeratotic lesions in the perineal area and often also on the extensor limbs.[55–57] The condition occurs in both sexes, and family studies suggest both autosomal dominant and autosomal recessive patterns of inheritance may be possible. Light microscopic evaluation of skin and mucosae shows dyskeratotic cells in the spinous layer, vacuolated basal cells, and lack of epithelial maturation.[55,57] Electron microscopy shows paucity of desmosomes, cytoplasmic vacuolization, and presence of multilaminar bands and wheat sheaf–like collections of filamentous fibers in the cytoplasm, resembling gap-junction material, and suggesting a disorder of desmosomal or gap junction proteins.[55] Recent studies of several characteristic cases in one pedigree found normal expression of gap junction proteins (connexins 26, 32, and 43), desmosomal proteins (desmogleins 1 and 2, plakoglobin, desmoplakins I and II, and plakophilin 1), adherens junction proteins (β-catenin and E-cadherin), and cytoskeleton proteins (keratins, β-tubulin, vimentin, and actin).[57] Genetic analysis in the studied family excluded the desmosomal cadherins in chromosome 18q12 as candidate genes and ruled out a mutation in connexin 26.[57]

Ichthyosis Follicularis, Alopecia (Atrichia), and Photophobia Syndrome

The association of ichthyosis follicularis, alopecia, and photophobia was first reported as a syndrome by McLeod in 1909,[58] and for many years additional reported cases of what came to be designated *IFAP syndrome* occurred in males. Affected individuals demonstrate widespread, flesh-colored, spiny, follicular projections with minimal, if any, inflammation, severe alopecia, often total atrichia involving eyebrows and lashes as well as scalp hair, and severe photophobia, often with demonstrable corneal vascularization.[15,59–62] The condition was postulated to be inherited as an X-linked recessive trait, which is supported by the report of the mother and sister of a male patient with classical features of IFAP syndrome having linear lesions of hyperkeratosis, hypohidrosis, and atrophy and a patchy scalp alopecia, distributed along Blaschko's lines.[63] Many patients have only cutaneous features, but neurologic and skeletal anomalies and recurrent infections have occasionally been described.[60,62,64–66]

Atypical cases have included females with generalized involvement and transmission from mother to daughter[64,67–69]; psoriasiform patches,[62,68,69] particularly involving the perineal area; and hypotrichosis rather than complete atrichia.[69] Some patients with psoriasiform plaques lack the typical spiny follicular projections[62,66] and may represent a different entity,[70] or even a variant of HMD.[69] In support of the latter is the ultrastructural finding of reduced numbers of desmo-

APPROACH TO THE PATIENT WITH HAIR GROWTH DISORDERS

AT A GLANCE

- Classify the hair disorder based on pathogenetic principles (see Table 86-2) and clinical pattern (see Table 86-4).
- Exclude or confirm the most common hair growth disorders based on pattern and diagnostic tools (see Table 86-3).
- Dispel misconceptions and educate the patient.
- Treat as appropriate for the confirmed or suspected diagnosis.
- Provide emotional support for patients who are adversely affected by the cosmetic effects.

guidelines for the assessment and management of patients with alopecia.[4,6,7]

PRINCIPLES OF HAIR FOLLICLE PATHOBIOLOGY

Hair growth disorders are best understood and managed if one recalls some basic concepts of hair follicle biology (for more details on hair follicle structure and function, see Chap. 84).

Clinically Relevant Hair Biology

Knowledge of the basic biology of hair enables essentially all hair growth disorders to become easily understandable as reflections of distinct pathogenetic mechanisms or combinations (Table 86-2).

Problems of the Hair Follicle Cycle

Disturbances of hair follicle cycling lie at the heart of most hair growth disorders, and have dramatic effects on visible hair growth and hair shaft shedding. If the anagen phase is prematurely terminated and catagen occurs too early, the affected skin shows largely catagen and/or telogen follicles, and loosely anchored club hairs that are eventually shed (i.e., the normal anagen/telogen ratio of approximately 4.5:1 changes in favor of telogen). Considering that our scalp skin alone has approximately 100,000 hair follicles, even relatively small shifts in the percentage of anagen versus telogen follicles have major effects on hair growth and shedding.

The resulting effluvium and alopecia is exemplified by drug- or hormonally induced telogen effluvium, or when inflammatory cells attack the anagen hair bulb in alopecia areata.[8,15] Alopecia areata offers a particularly instructive illustration of how crucial hair cycle disturbances are for hair loss: The hair-damaging inflammatory cell infiltrate almost exclusively attacks anagen hair bulbs; this immune attack then catapults anagen follicles into a dystrophic catagen, causing a major hair cycle disturbance and rapid shedding of the insufficiently anchored, improperly formed hair shafts.[22–24] As a result, the three most effective therapeutic strategies for hair loss therapy in the vast majority of patients that suffer from hair loss, in declining order of importance, are (see eFig. 86-0.2 in on-line edition):

1. To inhibit catagen development so as to prolong anagen.
2. To induce anagen in telogen follicles so as to increase the percentage of actively hair shaft-producing follicles.
3. To inhibit exogen so as to reduce hair shaft shedding.

Unfortunately, neither of the two currently available U.S. Food and Drug Administration–approved standard hair drugs (finasteride, minoxidil; see Treatment) are highly efficient and reliable catagen inhibitors or anagen inducers, and it is unknown whether they affect normal hair shedding ("exogen")[17] at all. Even 17β-estradiol, an important hair growth–modulatory hormone,[18] may inhibit catagen in human scalp hair follicles[25,26] more effectively than these standard "hair drugs." However, catagen inhibition can often simply be achieved by eliminating a catagen-inducing drug (e.g., β blockers, synthetic retinoids, anticoagulants, antithyroid drugs), by professional management of a catagen-inducing endocrine disorder (e.g., thyroid dysfunction, hyperandrogenism, hyperprolactinemia), or by adequate substitution therapy of a catagen-promoting deficiency (e.g., in iron, zinc, estradiol, or protein deficiency).[27–29]

Problems of Hair Follicle Transformation

Next to hair cycle abnormalities, the second most important cause of hair growth disorders involves the terminal-to-vellus or vellus-to-terminal transformation of hair follicles in a skin region where this does not normally occur spontaneously and/or is undesired. The former is the hallmark of patterned balding, which arises from the miniaturization of very large, well-pigmented

TABLE 86-1
Definitions

- Alopecia: Hair loss usually on the scalp
- Canities: Graying of hair
- Effluvium: Process of increased daily hair shaft shedding (normal: 25–100)
- Telogen hairs: Club hairs with depigmented rounded up proximal ends
- Anagen hairs: Hairs with pigmented malleable proximal ends
- Hair follicle cycle: Life-long cyclic transformations of the hair follicle, which begin in utero
- Catagen: Apoptosis-driven regression phase in between telogen and anagen phase
- Telogen: Period of relative quiescence, lasts variable periods of time depending on body site
- Anagen: Growth phase, lasts variable periods of time depending on body site
- Exogen: Active process of hair shaft shedding
- Hirsutism: Increased hair growth in male secondary sexual hair areas in a woman, restricted to strongly androgen-responsive hair follicles
- Hypertrichosis: Increased growth of terminal hairs in an area normally rich in vellus hairs
- Lanugo hair: Produced in utero, pigmented, in length and in form somewhere between vellus and terminal hair; occurrence in postnatal life (hypertrichosis lanuginosa) may indicate a serious problem
- Poliosis: Localized white hair
- Scarring alopecia: Cicatricial/permanent alopecia. Irreversible loss of hair follicles, with disappearance of follicular orifices, and potentially skin atrophy
- Terminal hair: Produced by large hair follicles located in the subcutis; hairs are generally > 0.03 mm in diameter
- Vellus hair: Produced by very small (but functionally fully active, cycling) hair follicles located in the dermis; thin (≤ 0.03 mm diameter), short, often depigmented, usually non-medullated hair shaft

TABLE 86-2
Pathogenesis Approach to Diagnosis

Pathogenetic Principle	Clinical Effect (Examples)
• Disturbed hair follicle cycling	Effluvium (telogen effluvium, alopecia areata, androgenetic alopecia, chemotherapy-induced alopecia)
• Unwanted hair follicle transformation	Patterned hair loss (androgenetic alopecia) Hirsutism Hypertrichosis
• Defective hair follicle regeneration	Cicatricial alopecia (lichen planopilaris, traction alopecia, radiation-induced alopecia, folliculitis decalvans, chronic discoid lupus erythematosus)
• Structural hair shaft defect	Hair shaft disorders (monilethrix, pili torti, trichothiodystrophy)
• Improper/missing hair follicle development	Aplasia cutis congenita Ectodermal dysplasias
• Combinations of the above	

Note that infectious or physical agents (e.g., staphylococci, dermatophytes, herpes–varicella zoster virus; ionizing radiation, trauma) or drugs that can lead to alopecia do so by inducing one or several of the above pathogenesis pathways (e.g., disturbed hair follicle cycling, structural hair shaft defect, defective hair follicle regeneration).

terminal hair follicles in androgen-sensitive scalp regions (i.e., vertex, temporofrontal skin) into minute, unpigmented, vellus hair follicles by dihydrotestosterone. This is usually, but not always, accompanied by telogen effluvium, due to the anagen-shortening effect of androgens (see eFig. 86-0.2 in on-line edition). The opposite transformation process underlies hirsutism, characterized by the excessive vellus-to-terminal transformation of androgen-dependent hair follicles in a male pattern, or as is seen in drug-, hormone-, or porphyrin-induced hypertrichosis.

Defects in Hair Follicle Regeneration

Permanent alopecia or cicatricial alopecia largely results from a defective capacity for hair follicle regeneration due to irreversible damage suffered by epithelial hair follicle stem cells. How exactly autoaggressive, inflammatory attacks on hair follicle stem cells are induced and regulated, how they may best be prevented, and how the recovery of these stem cells from immunologically or radiation-induced damage may be effectively promoted are all critically important, yet unanswered, questions.

Structural Hair Shaft Defects

Acquired or inherited defects in hair shaft production (e.g., from the expression of abnormal hair keratins or insufficient hair follicle supply with essential nutrients, trace elements, or vitamins) may lead to the generation of distorted, misshapen hair shafts during anagen. These structural changes may lead to hair fragility, with breakage soon after the hair penetrates the epidermal surface.

Alopecia Due to Improper or Missing Hair Follicle Development

Extremely rarely, as in aplasia cutis congenita (see Chap. 106) and in various forms of ectodermal dysplasias (see Chap. 143), hair follicles in defined regions of the integument have never developed properly. This must be distinguished from rare, inherited hair follicle abnormalities in which patients present with neonatal or early-onset alopecia, despite presumably normal intrauterine hair follicle development. This is true for the human equivalents of the well-known nude and hairless alopecia phenotypes seen in mutant mice. These conditions result from defined transcription factor defects that lead to improper hair shaft formation (nude/FOXN1)[36–38] or progressive hair follicle destruction with the onset of catagen (hairless)[39–42] after apparently normal hair follicle development.

DIAGNOSTIC TECHNIQUES

Hair loss confronts one with greater diagnostic challenges than disorders associated with excessive hair. It is optimal to follow established guidelines for considering and excluding the chief causes of effluvium and/or alopecia (Table 86-3; Fig. 86-1).[4,7] Using pattern recognition (Table 86-4) and focusing on pathogenic principles (see Table 86-2), one can use diagnostic procedures of increasing complexity (see Table 86-3) to reach a diagnosis. In general, the diagnosis is likely to be one of the four most common hair growth disorders [androgenetic alopecia (male or female pattern), telogen effluvium, alopecia areata, or hirsutism], rather than a rare diagnosis. The presence of "alarming hair signs" should be sought, and difficult differential diagnoses should be considered.

ALOPECIA: DIFFUSE (GLOBAL) HAIR LOSS

Reduced or absent hair growth in infancy may be the result of a failure of normal hair follicle development, and may be associated with other ectodermal defects (see Chap. 143). Many of these hereditary syndromes have other anomalies, most frequently bone, central nervous system, or eye. The features and mechanisms that underlie genetic disorders with hair abnormalities are discussed and regularly updated in the Online Mendelian Inheritance in Man website (http://www.ncbi.nlm.nih.gov/sites/entrez?db=OMIM).[47]

The most common of the ectodermal dysplasias, hypohidrotic ectodermal dysplasia, which is characterized by sparse hair, abnormal teeth, and reduced or absent sweating, is due to mutations in the ectodysplasin signaling pathway.[48] This pathway is involved in the early embryogenic events in formation of the hair follicle placode.[21,49,50] Ectodermal dysplasias and genetic hair disorders for which genetic loci have been identified are listed in, and are largely discussed in other chapters, particularly Chap. 143.

HAIR SHAFT ABNORMALITIES

Hair shaft abnormalities can be primary and hereditary or secondary to external factors. Some hair shaft abnormalities represent common endpoints to various forms of trauma or inherent shaft weaknesses, and some are specific to a particular constellation of findings or inherent make-up of the hair shaft. Hair shaft abnormalities can be divided into those associated with hair breakage and those associated with unruly hair.

Hair Shaft Abnormalities Associated with Hair Breakage

TRICHORRHEXIS NODOSA The most common defect of the hair shaft leading to hair breakage is trichorrhexis nodosa.[51] Mechanical or chemical damage triggers this response, which can occur in nor-

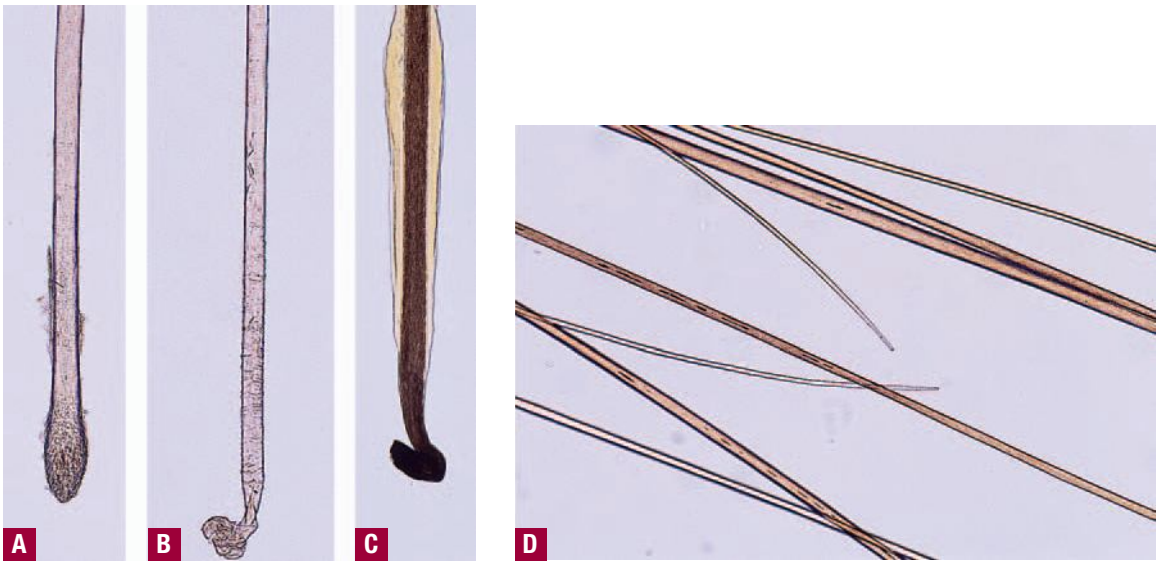
TABLE 86-3
Diagnostic Procedures

- Essential procedures
  - Hair pull test to assess scalp hair cycling
    - Manually grasp 50–100 scalp hairs and apply gentle traction from the base to the terminal ends, repeating in various areas of the scalp.
    - Shedding of more than two hairs/hair pull on multiple hair pulls is pathologic, if hair has been shampooed regularly.
    - To assess easy breakage or brittleness of hair if suspect structural hair shaft defect, hold hair shafts at both ends, and pull in opposite directions or rub hair between fingers.
  - Hair shaft microscopy
    - Align proximal portions of collected hairs on slide in a drop of cyanoacrylic glue, apply coverslip; alternative technique is to let hair shafts swell on glass slide in a drop of tap water under coverslip for 10 min before inspection.
    - Evaluate the proximal ends of pulled hairs for intact shaft and bulb, or hair breakage.
    - Assess if normal telogen club hairs (physiologic aberration; see Fig. 86-3A) versus dystrophic telogen or anagen hairs (pathologic process; see Fig. 86-3B).
  - Dermatoscope
    - Search for signs of scarring and a quick look at hair shaft details.
  - Biopsy (mandatory if scarring alopecia is suspected; insight into mechanism)
    - Take one to two 4-mm or one 6-mm punch biopsy in the direction of the follicle growth (oblique angle) and to a sufficient depth to contain the follicular bulbs in anagen located in the subcutis. The 6-mm punch should be bisected.
    - Vertical and horizontal sections have different uses: Vertical sectioning gives one a view of the epidermal/dermal interface, and horizontal sections allow quantitative assessment of the hair density.
- Additional useful tests
  - Trichogram (hair pluck test)
    - Rarely done today. Quick pull of 50–100 hairs en masse using a clamp or needle holder. Inspection of proximal hair bulbs allows determination of anagen/telogen ratio, but fraught with procedural artifacts, fails to give critical information about the type of hair being shed, and yields small sample size.
  - Phototrichogram (objective hair cycle assessment)[5]
    - To determine (1) the percentage of hairs in anagen, (2) the growth rate (with sophisticated cameras and computer software), and (3) shaft diameter requires locating the same precise target site at each time point, standardized photography, and standardized hair counting by image analysis.
    - Hairs are shaved in a demarcated target area and comparative photographs done at baseline and 2–3 days later. Only anagen hairs increase their length on follow-up (normal hair growth is ~ 1 cm/mo).
  - Global hair photography
    - Assesses the global cosmetic appearance of scalp hair in a defined area (vertex, frontotemporal, occipital) under precisely standardized conditions (constant distance, angle, and lighting) before, during, and after therapy. Optimal for independent, blinded assessments of therapeutic success or failure.
  - Hair shedding count
    - Standardized hair loss count before and 3 months after therapy.
    - Day 1: shampoo vigorously; days 2–4: no shampooing, comb only once a day. For these 3 days, have patient collect (1 envelope/day) and count only hair shafts lost during combing once daily.
  - Potassium hydroxide stain (for suspected fungal infection)
    - May reveal spores and hyphae in plucked proximal shafts. Complement with standard mycologic cultures.
    - Wood's lamp (see Chapter 5)
  - Laboratory tests
    - Most commonly performed for hair loss: complete blood cell count, ferritin or iron/total iron binding capacity, thyroid-stimulating hormone, and thyroxine
  - Additional tests as suggested by history and examination
    - Testosterone, dehydroepiandrosterone, sex hormone–binding globulin, prolactin, anti-nuclear antibody, double-stranded DNA, C-reactive protein, erythrocyte sedimentation rate, VDRL/treponemal hemagglutination.
  - Complementary techniques for hair shaft abnormalities
    - Most hair shaft abnormalities can be diagnosed by light microscopic examination, although some types require scanning electron microscopy to confirm findings suggested by light microscopy (e.g., longitudinal grooving), or to definitively rule out (e.g., monilethrix). Polariscopic examination should be performed if trichoschisis (a particular pattern of hair breakage) is seen under light microscopy to evaluate potential trichothiodystrophy (sulfur-deficient hair). The etiology of brittle hair can be further pursued by direct amino acid analysis of whole-hair hydrolysates and electrophoretic characterization of the main classes of proteins in hair (generally defined by their cysteine content, and designated ultrahigh-, high-, and low-cysteine or ultrahigh, high-, and low-sulfur proteins).

Data from Olsen EA: Current and novel methods for assessing efficacy of hair growth promoters in pattern hair loss. . %Q %GH(I VQES48:253, 2003.

mal hair, but occurs much more readily in inherently weak hair. Microscopically, the affected hair develops a breach in the cuticle, with eventual separation and fraying of the exposed cortical fibers leading to a nodal swelling.[52] The fibers then fracture and the shaft breaks with the resultant appearance of a splayed paintbrush or fan-like array (Fig. 86-2). Trichorrhexis nodosa may be congenital or acquired.

Congenital trichorrhexis nodosa may be present at birth or may appear within the first few months of life. Although it might occur as an isolated defect or, rarely, with follicular hyperkeratosis or teeth/nail defects,[51] the occurrence of congenital trichorrhexis nodosa should lead to a search for an underlying metabolic disorder. Patients with argininosuccinic aciduria (see Chap. 131), primarily those with the late-onset form (occurring at more than 2 years of age),[15] have associated hair defects. In this condition, in which absence of the enzyme argininosuccinase leads to an accumulation of the nitrogenous waste precursor argininosuccinic acid, brittle lusterless hair develops along with psychomotor retardation and ataxia. The diagnosis is established by finding acidosis, hyperammonemia, and low serum arginine.[53] Citrulline (the normal precursor of argininosuccinic acid in the urea cycle) accumulates in the condition citrullinemia (see Chap. 131), which is caused by a defect in the enzyme argininosuccinic acid synthetase. In this condition, the hair is brittle and both trichorrhexis nodosa and pili torti (another common hair shaft defect) may be present.[51,54] Affected infants have an associated dermatitis that may be widespread but more pronounced in the perioral and diaper area. Patients with Menkes syndrome, caused by a defect in copper efflux,[55] and trichothiodystrophy (TTD; see Chap. 47), caused by a defect in the synthesis of the ultrahigh- and high-sulfur proteins integral to hair,[56] both have tri-



▲ **FIGURE 86-1** **A.** Telogen club hairs have a cornified, depigmented, rounded-up bulb without an attached root sheath. **B.** Loose anagen hair obtained by hair pull: Ruffled cuticle and no attached root sheath. Anagen hairs are recognized clinically by their pigmented, somewhat distorted, malleable bulb. Anagen hairs should not normally be found in a hair pull in patients with alopecia areata. **C.** Comparison with a normal anagen hair obtained by hair pluck. **D.** A newly growing anagen hair has a tapered distal tip rather than the blunt distal end of hairs that have been cut or trimmed or ends that are intrinsically broken.

chorrhexis nodosa apparent on microscopic examination of the associated brittle hair.

Acquired trichorrhexis nodosa, which is much more common than hereditary trichorrhexis nodosa, may be either distal or proximal. Proximal breakage appears most commonly in African American women, usually after repetitive chemical or hot-comb straightening.[51] Distal trichorrhexis nodosa is more commonly secondary to excessive brushing, back-combing, or sporadic use of permanent waves. Treatment of trichorrhexis nodosa, congenital or acquired, is by avoidance of chemical or physical trauma to the hair.

TRICHOSCHISIS The break in trichoschisis is a clean transverse fracture through the entire hair shaft at a location where there is a focal absence of cuticle (Fig. 86-3). Trichoschisis is usually, but not specifically, a marker for the sulfur-deficient hair of TTD, in which the hairs of the scalp, eyelashes, and brows are short and brittle.[51] The hair abnormality of TTD identifies a group of autosomal recessive disorders in which acronyms or eponyms identify particular constellations of extratrichologic neuroectodermal abnormalities (Table 86-5). In affected individuals, the hair cystine content is less than one-half normal, primarily from a major reduction and altered composition of the ultrahigh-sulfur matrix proteins.[56] Polariscopic examination of affected hairs characteristically shows alternating light and dark bands, presumably secondary to variations in sulfur content (see Fig. 86-3).[51] Various structural abnormalities can be detected by confocal and scanning electron microscopy, whereas Raman spectroscopy shows a larger contribution of energetically less favored disulfide conformers in TTD hairs. Taken together, these complex abnormalities make TTD hairs excessively prone to breakage and weathering.[57] Sulfur and/or amino acid analysis of the hair is diagnostic.

Patients with TTD, particularly the 50 percent with associated photosensitivity, may have a defect in excision repair of ultraviolet (UV) damage but without an increased risk of skin cancer.[58] Recent data support correlation of mutations in the DNA repair and transcription gene ERCC2 locus with the nucleotide excision repair characteristics of both TTD and xeroderma pigmentosum (see Chap. 140).[25] No treatment is currently available, but photosensitive patients should be tested for their cellular response to UV radiation and encouraged to practice sun protection.

PILI TORTI The short and brittle hairs in patients with pili torti, when viewed through a microscope, appear flattened and twisted through 90° to 360°.[51] The twisting must be differentiated from the normal twisting in the hair of black individuals and in the pubic/axillary hairs of other races; the hairs are distinguished by the multiple irregular intervals of twisting along an otherwise straight hair shaft (Fig. 86-4A). As with trichorrhexis nodosa, pili torti does not signify a particular abnormality but can be seen in many different syndromes and in the presence of other hair shaft abnormalities. Hereditary pili torti as an isolated finding, usually autosomal dominant, but potentially autosomal recessive or sporadic, is present at birth or develops over the first 2 years of life (see Fig. 86-4B). Clinically, the patient may have patchy alopecia with coarse stubble or longer broken hairs. The hair abnormality may improve after puberty. Pili torti, or a facsimile best characterized as "twisting hair dystrophy,"[26] may occur with other abnormalities. Particularly notable is the association of pili torti with Menkes syndrome (which results from inherited loss-of-function mutations in the gene encoding a copper-transporting adenosine triphosphatase (Atp7a) on the X chromosome[59] or trichopoliodystrophy. Infants with Menkes syndrome develop sparse, depigmented brittle hairs that show pili torti or trichorrhexis nodosa on microscopic examination.[51] The affected child characteristically has pale, lax skin, and mental and neurologic impairment secondary to degeneration of cerebral, cerebellar, and connective tissue.[60] In this X-linked recessive disorder, the defective gene, MKN or ATP7A, which maps to Xq13.3, encodes a copper-translocating membrane protein adenosine triphosphatase that prevents effective copper transport and leads to the accumulation of intracellular copper in

some tissues.[55] The excessive intracellular copper inappropriately triggers the synthesis of metallothionein, whose normal function is to chelate copper to prevent cellular toxicity. This further deprives the copper-requiring enzymes of the copper needed for normal function.[61] A low serum level of ceruloplasmin is diagnostic. Copper replacement is ineffective in preventing the inevitable progressive and lethal neurologic decline, but copper-histidine given immediately postpartum may prevent or ameliorate the severe neurodegeneration.[62]

▲ **FIGURE 86-2** Trichorrhexis nodosa.

TRICHORRHEXIS INVAGINATA ("BAMBOO HAIR") Bamboo hair is a distinctive hair shaft abnormality that may occur sporadically, either in normal hair or with other hair shaft abnormalities, or regularly as a marker for Netherton syndrome. The primary defect appears to be abnormal keratinization of the hair shaft in the keratogenous zone, allowing intussusception of the fully keratinized and hard distal shaft into the incompletely keratinized and soft proximal portion of the shaft.[63] This leads to the typical "ball-and-socket" deformity (Fig. 86-5) or, if fracture of the shaft occurs, a golf tee–shaped distal end of the shaft. Netherton syndrome (see Chap. 47) is an autosomal recessive–inherited disorder consisting of a triad of ichthyosis, atopic diathesis, and trichorrhexis invaginata.[51] Affected hairs are generally short and brittle and may be irregularly distributed over the scalp; this may lead to potential sampling errors on hair shaft evaluation.

MONILETHRIX The hair abnormality of monilethrix is distinctive, with extremely short, brittle hairs emerging from keratotic follicular papules (see Fig. 85-5 and Chap. 85).[67] The onset may be delayed until patients are in their teens, and the loss may be localized or diffuse. Microscopically, hairs show elliptic nodes with a regular periodicity of 0.7 to 1.0 mm (Fig. 86-6).[51] Between the nodes, the hair shaft is constricted, and it is in these areas that the hair usually fractures. Monilethrix is caused by mutations of one of three of the genes encoding type II hair cortex keratins (KHb1, KHb3, and Khb6). Rare cases that clinically resemble monilethrix are autosomal recessive; the underlying gene, desmoglein 4 (DSG4), belongs to the desmosomal cadherin superfamily and is also expressed in the cortex of the hair follicle.[68,69]

Most cases of monilethrix are of autosomal dominant inheritance, with variable expressivity. In the mildest cases, the hair defect is localized to the occiput.[15,70] The hair defect may occur alone or in association with keratosis pilaris, physical retardation, syndactyly, cataracts, and nail/teeth abnormalities. Retinoids and topical minoxidil may be useful treatments, although this condition may also improve spontaneously with age.

LOCALIZED AUTOSOMAL RECESSIVE HYPOTRICHOSIS Localized autosomal recessive hypotrichosis results from a mutation in the gene for desmoglein 4 (dsg4), a desmosomal protein.[71] Patients present in early childhood with sparse broken hair involving scalp and eyebrows, and follicular hyperkeratosis (keratosis pilaris). The clinical presentation resembles monilethrix but the hair shafts do not show beading (Fig. 86-7).

Hair Shaft Abnormalities Associated with Unruly Hair

UNCOMBABLE HAIR SYNDROME The distinctive hair of patients with uncombable hair syndrome may present any time from infancy to puberty. The slow-growing, silvery blonde, "spun-glass" hair is generally unmanageable and disorderly but not unduly fragile (Fig. 86-8A).[15,72] The condition may be autosomal dominant or sporadic. Under light microscopy, the hair appears normal or may have some suggestion of a longitudinal groove or ribbon-like flattening (see Fig. 86-8B). Scanning electron microscopy confirms a longitudinal groove, and the hair may, if viewed on cross-section, show a kidney bean or triangular shape, which accounts for the alternate term of pili triangulati et canaliculi. The longitudinal groove in the hair shaft

Short Anagen Syndrome

The term *short anagen syndrome* has been applied to a poorly understood clinical presentation characterized by short fine but otherwise normal hair in children.[85] Hair density is normal, and there are no associated features. It is usually sporadic, although families showing autosomal inheritance have been described. Hair growth may improve after puberty.

Acute Telogen Effluvium

Acute telogen effluvium may occur at any age and represents a precipitous shift of a percentage of anagen hairs to telogen.[86] Telogen effluvium is a reaction pattern to a variety of physical or mental stressors[1,12,87,88]; the most common causative factors are given in Table 86-6. Although the clinical evidence that psychoemotional stress can cause telogen effluvium is still weak, the fact that defined stressors have very profound hair growth-inhibitory effects in mice[87,88] and that the central hypothalamic stress hormone, and the key stress-associated growth factor, nerve growth factor, both significantly inhibit human hair growth and prematurely induce catagen development in vitro[88,89] renders it likely that "stress" is also a negative hair growth modulator in humans. Any drug can potentially cause telogen effluvium, although some classes of drugs routinely do so.

TABLE 86-6
Causes of Telogen Effluvium

- Endocrine
  - Childbirth, miscarriage, abortion
  - Hypo- and hyperthyroidism
  - Discontinuation of estrogen-containing drugs
- "Stressful" events
  - Febrile illnesses
  - Catabolic illnesses (e.g., malignancy, "consumptive" chronic infection)
  - Major surgery
  - Major trauma
  - Acute or chronic psychological stress
- Nutritional
  - Rapid weight loss (e.g., "crash dieting")
  - Caloric or protein deprivation
  - Chronic iron deficiency
  - Excessive vitamin A ingestion
- Intoxication
  - Thallium
  - Mercury
  - Arsenic

  - Penicillamine
  - Retinoids
  - Selective serotonin reuptake inhibitors
  - Valproate
- Inflammatory scalp disease
  - Seborrheic dermatitis
  - Erythroderma

Normally, 50 to 100 hairs are shed per day. In telogen effluvium, a clinical increase in scalp hair shedding usually begins as the first group of anagen hairs that were thrown prematurely into telogen enter exogen 3 to 4 months after the inciting event. If the inciting cause is removed, the shedding resolves spontaneously over the next several months as the percentage of hairs in telogen return to normal; however, the hair density may take 6 to 12 months to return to baseline. In a significant number of patients, no obvious cause is found for telogen effluvium, and the increased shedding, and concomitantly the decreased density, of the scalp hair may become chronic.[90] Acute telogen effluvium is always potentially reversible and does not lead to total scalp hair loss, as the percentage of hairs in telogen rarely goes beyond 50 percent (Fig. 86-10). Persistent excess hair shedding after an acute episode may be an indication of other pathology, most commonly early female pattern hair loss and/or thyroid malfunction.

Chronic Telogen Effluvium

A persistent form of telogen effluvium, with loss of hair volume, lasting in excess of 6 months typically occurs in middle-aged women who may bring large amounts of shed hair for examination at a clinic visit.[91] Examination shows normal or high hair density, although there may be some rarefaction with short hairs along the frontotemporal regions. A simple method for evaluating shed hairs based on their length and the number of shed hairs per day has been proposed to help distinguish chronic telogen effluvium from androgenetic alopecia,[92] with the latter being associated with length less than 3 cm and fewer shed hairs per day. Underlying disorders, such as thyroid deficiency and systemic lupus erythematosus (SLE), should be excluded. Iron deficiency, with or without anemia, is often cited as a cause of chronic telogen effluvium,[93] although this is still controversial.[94,95] In one study, the mean ferritin level was significantly lower in patients with androgenetic alopecia than in normal controls without hair loss, but this was not seen in patients with telogen effluvium.[94]

▲ **FIGURE 86-10** Telogen effluvium.

In some women, chronic telogen effluvium is an early feature of androgenetic alopecia, and up to 60 percent of women with chronic telogen effluvium may show histologic evidence of pattern hair loss on biopsy.[96] In many women, however, no cause can be established and excess shedding may simply be the result of an age-related shortening of the hair cycle[97] that cannot reliably be distinguished from androgen-dependent anagen shortening, suggesting a relationship.[15] Retinoid-induced telogen effluvium has been the trigger for the development of androgenetic alopecia in older teenagers and young adults treated for acne.

Excessive hair shaft shedding and diffuse, non-scarring hair loss is a common feature of SLE (see Chap. 156), which occurs in 24 percent to 84 percent of SLE patients.[98–100] The degree of (telogen) effluvium is often associated with SLE activity, and patients with SLE may go on to develop cicatricial alopecia from chronic discoid lesions [see the section Cicatricial Alopecia (Destruction of the Follicle)].[101]

Anagen Effluvium

The daily loss of some telogen hairs is entirely normal, but it is always abnormal to shed anagen hairs. The term *anagen effluvium* is somewhat misleading because the abnormal anagen hairs in this condition are usually broken off rather than shed. The anagen hairs in

loose anagen syndrome and those of alopecia areata are generally shed in toto.

The classic and easily recognizable causes of anagen effluvium of the scalp are radiation therapy to the head and systemic chemotherapy, especially with alkylating agents (e.g., cyclophosphamide).[102,103] These agents can impair or totally disrupt the anagen cycle and cause varying degrees of hair follicle dystrophy.[104] The net result is either anagen hairs that break off within the follicle or at the level of the scalp (secondary to a weak point in the structurally inferior hair shaft) and are then shed without roots, or dystrophic anagen hairs that are easily dislodged from the usual follicular moorings. Replacement with a normal pelage usually occurs rapidly after discontinuation of chemotherapy, although high-dose busulfan as part of the preparatory treatment for bone marrow transplantation may lead to permanent alopecia due to irreversible damage to hair follicle stem cells.[5,105,106] Regrowth after radiation therapy depends on type, depth, and dose-fractionation, yet commonly leads to permanent follicular destruction, most likely as a result of irreversible hair follicle stem cell damage. In fact, scarring alopecia may progress long after radiation therapy has been discontinued, possibly due to persistent radiation-induced inflammatory changes that progressively damage hair follicle stem cells.[102] Lower dose cytostatic regimens or administration of less cytotoxic agents (e.g., methotrexate, dacarbazine) more often cause only telogen effluvium, because they induce premature catagen.

Cooling caps were previously advocated as a preventive measure for chemotherapy-induced alopecia,[107] but are relatively ineffective and poorly tolerated. The pharmacologic management of chemotherapy-induced alopecia has remained highly unsatisfactory.[5,103]

In the absence of obvious causes of anagen disruption such as cytostatic agents, one must consider exposure to toxic agents. Mercury intoxication, through either chronic industrial exposure, consumption of polluted water or seafood, or inadvertent exposure to mercury-containing antiseptics or fungicides, can lead to hair loss with or without other symptoms, especially neurologic ones.[111] Diagnosis is by documenting elevated mercury levels in hair, blood, or urine. Boric acid intoxication may be through exposure to household pesticides or ingestion of some common household products in which boric acid is a preservative. Patients may develop hair loss along with gastrointestinal, central nervous system, and renal symptoms; a hemorrhagic diathesis; and exfoliation or bullae.[102,112] Blood boric acid levels are elevated in affected patients.

Thallium poisoning leads to dramatic hair loss, with complete epilation occurring 2 to 3 weeks after intoxication.[113] Acutely, patients experience primarily neurologic symptoms including irritability, dysesthesia, ataxia, convulsions, and coma. Blood and urine levels are positive at the time of acute poisoning. Toxic exposure to colchicine and ingestion of certain plants can lead to anagen loss.[102] Severe protein malnutrition may also lead to anagen effluvium. Arsenic exposure does not cause hair loss; instead, arsenic is concentrated in the hair, which facilitates a diagnosis long after intoxication may have occurred.

Loose Anagen Syndrome

Loose anagen syndrome, a recently described, but not uncommon, syndrome has been primarily described in fair-haired children who have easily dislodgable hair (Fig. 86-11A).[114,115] However, loose anagen syndrome can occur in adults and may be familial. Families frequently report periods of greater scalp hair shedding or quiescence. The hair loss may be inapparent, except when traumatic pulling or extraction easily dislodges clumps of hair. Parents of affected children often show a mild form. The hair may also present with unruliness, especially at the occiput, which can be confused with uncombable hair syndrome or woolly hair (see Fig. 86-11B).[116,117] This condition can be misdiagnosed as telogen effluvium if the shed hair roots are not examined microscopically. Microscopically, the proximal shed hair shows a normal anagen bulb, with a ruffled cuticle but without the usual attached root sheath.[118] The unruly hair generally shows a longitudinal groove in the shaft as in uncombable hair syndrome. Given the disruption of the bulb structure by plucking of the hair, it is critical to gently run the fingers through the hair to collect samples, rather than plucking; obviously, hair is easier to obtain during a period of active shedding. A scalp biopsy, which is unnecessary for diagnosis, may show premature and abnormal keratinization of the inner root sheath, with clefts between the inner and outer sheath and the hair shaft. At least in some patients with loose anagen syndrome, this typical gap may result from hereditary keratin defects in the inner root sheath and/or the apposed companion layer (e.g., in families with diffuse partial woolly hair that can be associated with loose anagen hair syndrome).[119] The hair loss may improve with age, and gentle handling decreases shedding.

▲ **FIGURE 86-11** Loose anagen syndrome. **A.** Diffuse hair loss. **B.** Unruly hair. (From Olsen EA et al: The presence of loose anagen hairs obtained by hair pull in the normal population. . -FZ VWA (I VQEXSP7] QT 4VSG4:258, 1999, with permission.)

ALOPECIA AREATA

Epidemiology

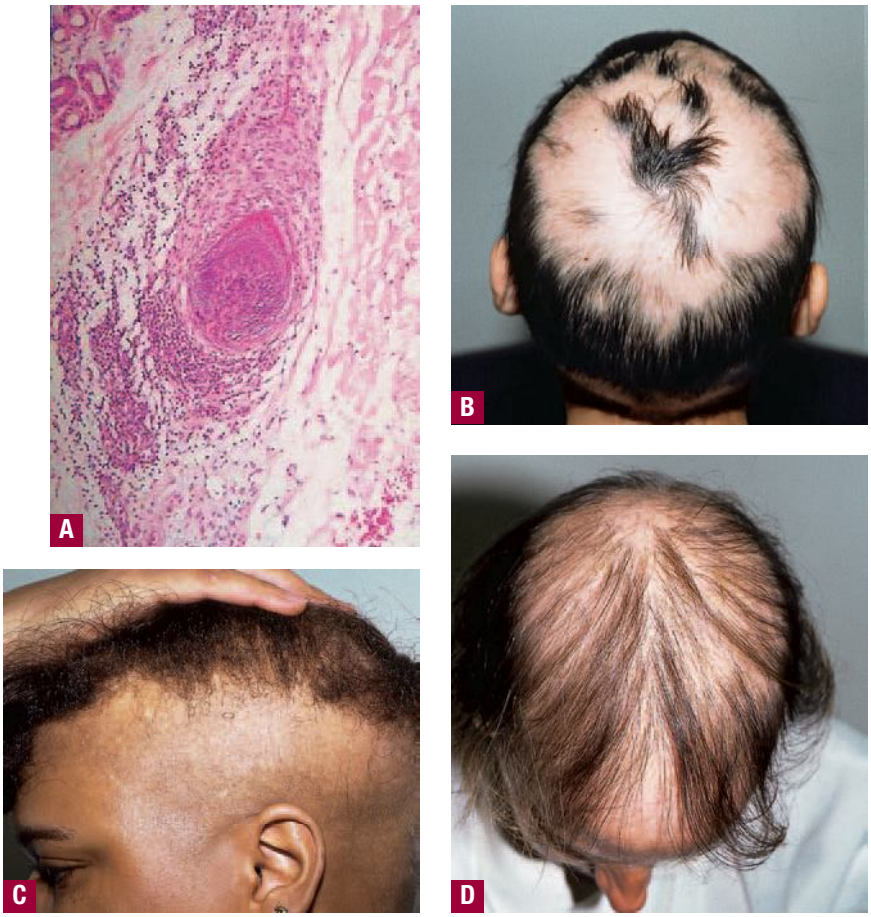
At any given time, approximately 0.2 percent of the population has alopecia areata and approximately 1.7 percent of the population experiences an episode of alopecia areata during their lifetime.[120,121] However, there are great geographic and ethnic variations in the incidence and prevalence of the disease; this is also seen with respect to the immunogenetic background of patients with alopecia areata.[24,43,76,122–127] In most patients, the onset is within the first three decades of life although alopecia areata can start at any age. The sex incidence is probably equal.

Etiology and Pathogenesis

Alopecia areata is a chronic, organ-specific autoimmune disease, probably mediated by autoreactive T cells, which affects hair follicles and sometimes the nails.[23,128–130] There is an increased frequency of other autoimmune diseases, notably autoimmune thyroid disease in affected adults, and of organ-specific autoantibodies in patients with alopecia areata.[129,131] Hair follicle autoantibodies are also found in some patients with alopecia areata[31,132] although it is unlikely that these autoantibodies are of importance in the primary pathogenesis of alopecia areata.[128,129,133]

Studies using human hair follicles transplanted into the skin of immunodeficient mice have provided convincing evidence for a cell-mediated etiology, with a key role for $CD8^+$ T cells, which may recognize a major histocompatibility complex class I–presented autoantigen (possibly expressed during anagen and/or anagen-associated melanogenesis).[129,134,135] These experimental data are in line with the concept that a (e.g., interferon-γ–induced) collapse of the normal immune privilege of the anagen hair bulb plays a key role on the primary pathogenesis of the disease.[128,130,133,136] Evidence in support of the concept that melanogenesis-associated autoantigens, which are normally sequestered from immune recognition by a functional hair follicle immune privilege, may be a key target of autoaggressive inflammation in alopecia areata[133] is slowly accumulating.[137,138] Histologically, alopecia areata is characterized by an inflammatory infiltrate, comprised mainly of T cells, in and around the bulbs of anagen hair follicles (Fig. 86-12A). The histopathologic features of alopecia areata, however, are stage-dependent, and the classic features may be missing in subacute and chronic lesions, rendering it prudent to include alopecia areata in the differential diagnosis whenever high percentages of telogen hairs or miniaturized hairs are present, even in the absence of a peribulbar lymphocytic infiltrate.[139]

Anagen follicles attacked by this inflammatory infiltrate move prematurely into catagen, followed by telogen, and then enter a dystrophic anagen status. Most follicles may continue to cycle but, while the disease remains active, are unable to progress beyond an early stage of anagen development and thus do not produce normal hair shafts.[140] An important feature of the pathology is that hair follicles are not destroyed in alopecia areata, possibly because the disease spares the follicular stem cell compartment in the mid-outer root sheath region.



▲ **FIGURE 86-12** **A.** Peribulbar lymphocytic infiltrate in alopecia areata. **B.** Extensive patchy alopecia areata. **C.** Ophiasis pattern of alopecia areata. **D.** Diffuse pattern of loss in alopecia areata. (**B-D** are reprinted with permission from Hordinsky MK: Alopecia areata, in (MSAH VWS), EVH+VS[X. (MEKRSVMWERH 8VEXQI Redited by Olsen EA. New York, McGraw-Hill, 1994.)

The predisposition to alopecia areata is genetically determined.[141] Between 10 percent and 20 percent of patients with alopecia areata give a family history of the disease, and the true figure is probably higher because mild cases may pass unnoticed or are concealed.[124] There are several reports of alopecia areata in twins, some with concurrent onset. One small study of alopecia areata in twins found a concordance of 55 percent in monozygotic twins but none in dizygotic twins.[142] The genetic predisposition is polygenic in nature. To date, most genes found to be associated with alopecia areata are involved in regulating immune responses, yet there are substantial geographic/ethnic differences in the immunogenetics of alopecia areata.[76,122–127,141] The strongest associations have been with genes of the HLA-D region of the major histocompatibility complex locus.[143,144] There is also an association between severe forms of alopecia areata and polymorphisms in the autoimmune regulator gene on chromosome 21.[145] Alopecia areata is common in Down syndrome,[146] and there is also a high frequency of the disease (more than 30 percent) in autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia syndrome (also called *autoimmune polyglandular syndrome-1*), a usually autosomal recessive disorder in which there are mutations in the autoimmune regulator gene (see Chap. 144).[147]

A variety of environmental factors, including infection, drugs, trauma, and stress, have been suggested as triggering alopecia areata, although most patients with alopecia areata are unaware of any obvious precipitating factor. It is possible, though hard to prove, that a diversity of insults, physical or psychological, may trigger episodes of alopecia areata[128] but there is no evidence that they influence the prognosis.

Clinical Features

Alopecia areata typically presents with round patches of hair loss. Patches may be single or multiple, and may coalesce (see Fig. 86-12B–D). Although most obvious on the scalp, any hair-bearing skin can be affected, and is frequently found to involve the beard area. The term *alopecia totalis* is used to describe complete loss of terminal hair on the scalp and *alopecia universalis* to describe total loss of all terminal hair on the scalp and body.[148] *Ophiasis* refers to a band-like pattern of hair loss at the periphery of the scalp (see Fig 86-12C). The scalp usually appears normal. The pathognomonic "exclamation mark" hairs may be present, particularly at the periphery of areas of hair loss (Fig. 86-13A). These short broken hairs, whose distal ends are broader than the proximal ends, illustrate their inherent sequence of events: follicular damage in anagen and then a rapid transformation to telogen. White or graying hairs are frequently spared and probably account, in cases of fulminant alopecia areata, for the mysterious phenomenon of "going gray overnight" (see Fig. 86-13B). Nails in patients with alopecia areata may show fine pitting or, less commonly, mottled lunula, trachyonychia, or onychomadesis (see Chap. 87).

Differential Diagnosis

Though the clinical diagnosis is usually straightforward, other conditions that typically need to be considered are:

- Tinea capitis. Obvious inflammation (e.g., scaling, pustules) in association with patchy hair loss suggests a diagnosis of tinea capitis and excludes alopecia areata.
- Trichotillomania. This can be difficult to distinguish from alopecia areata (and may, in fact, be associated with it, especially in children). However, here the hair loss is rarely complete and the broken hairs are usually firmly anchored in the scalp, unlike exclamation point hairs. A biopsy may be needed.
- Early scarring alopecia.
- Syphilis (alopecia areolaris).

Diffuse alopecia areata can be difficult to differentiate from other causes of diffuse hair loss, and may be associated with them (e.g., thyroid abnormalities, other autoimmune diseases and syphilis). Diffuse alopecia areata usually progresses rapidly and the diagnosis becomes clear with time, but a biopsy may be necessary to clarify remaining uncertainties.

Prognosis

Spontaneous remission can be expected in the majority of cases where hair loss is limited to a few small patches (possibly, up to approximately 80 percent within 1 year), although most patients experience recurrences at some stage.[149] The prognosis in extensive alopecia areata, particularly alopecia totalis and universalis, is less favorable and fewer than 10 percent of patients in the latter two groups recover spontaneously. The ophiasis pattern of alopecia also tends to be recalcitrant. Other features pointing to a poor prognosis include onset in childhood, loss of body hair, nail involvement, atopy, and a positive family history for alopecia areata.

Management

Counseling of patients on the nature of alopecia areata, its prognosis, and the treatment options is essential. For the majority of patients, alopecia areata is a cosmetic issue. Occasionally, it causes physical disability (e.g., when there is eyelash involvement or marked nail dystrophy). Nevertheless, the cosmetic importance of hair is such that alopecia areata can cause severe emotional problems, particularly in children and young women, though by no means restricted to these groups.[2] In view of the limited efficacy of current forms of treatment, the physician has an important role in helping patients adapt to their lack of hair. This is not an easy task and input from other health professionals, such as a clinical psychologist, may be needed. Many patients are helped by involvement in patient support groups. With children, it is often the parents whose reactions must be addressed for the child to adjust to the hair loss. The National Alopecia Areata Foundation (http://www.naaf.org) is an excellent source of information for patients.

Treatment

There is relatively little evidence from well-designed clinical trials, and so treatment recommendations are based mainly on case series and clinical experience (Box 86-1).[150] Helpful guidelines for managing alopecia areata have been developed.[4,6]

Box 86-1

Treatment of Alopecia Areata

- Patchy alopecia
  - Intralesional corticosteroids: Up to 2 mL injected/session and repeated at intervals.
  - Potent topical steroid 1–2 »/day.
  - Topical anthralin 0.1%–2.0% once daily. Wash off after 10–20 min, steadily increase contact duration, switch to higher dose if no significant irritation.
  - Minoxidil lotion (5%) twice daily.
- Extensive or rapidly progressive alopecia.
  - Contact immunotherapy.
  - Systemic corticosteroids. Benefits are uncertain and must be weighed against risk of systemic corticosteroid therapy.
  - Wig or hairpiece.
- Alopecia totalis/universalis
  - Contact immunotherapy.
  - Topical/systemic steroids.
  - Wig or hairpiece.

CONSERVATIVE MANAGEMENT All of the currently available treatments for alopecia areata have a high failure rate and none alters the natural history of the disease. After discussion of the options patients may therefore opt not to be treated, other than to wear a wig if appropriate. 'No treatment' is a legitimate option in patients with a short history and limited disease, in view of the high rate of spontaneous remission in this group.

TOPICAL CORTICOSTEROIDS Topical corticosteroids are widely used to treat alopecia areata. There is some evidence of efficacy if potent corticosteroids are used under occlusion,[151] but less aggressive treatment regimens are probably ineffective.

INTRALESIONAL CORTICOSTEROIDS Intralesional corticosteroids are the most effective approach for treating patchy alopecia areata. Hydrocortisone acetate (25 mg/mL) and triamcinolone acetonide (5 to 10 mg/mL) are commonly used, either by subdermal injection or using a needle-less device.[152,153] Multiple injections repeated monthly are usually necessary, limited by patient discomfort. Intralesional corticosteroids are not appropriate in rapidly progressive or extensive disease. Especially with triamcinolone injections, there is a significant risk of inducing skin atrophy, which may increase exponentially with each repeated injection.

SYSTEMIC CORTICOSTEROIDS Oral corticosteroid therapy can induce short-term hair regrowth in patients with alopecia areata; however, hair regrown is usually lost after treatment is discontinued.[154] Newer regimens that involve pulsed oral corticosteroids (e.g., prednisolone 200 mg once weekly for 3 months or dexamethasone 5 mg daily for 2 consecutive days/week for 3 months) may also induce hair regrowth in some patients. No significant side effects have been reported in published series but cannot be ruled out, and long-term benefits have not been shown.[150,155,156]

TOPICAL MINOXIDIL SOLUTION There is limited clinical trial evidence that topical minoxidil solution (TMS) stimulates hair regrowth in some patients.[3,157] Minoxidil is ineffective in alopecia totalis/universalis.

ANTHRALIN Data from small case series suggest that treatment with anthralin cream is helpful in some cases, but the overall response rate is low.[158] However, especially in children where steroids or contact immunotherapy are decided against, this is a reasonable and safe treatment option.

PHOTO(CHEMO)THERAPY Phototherapy using UVB has been widely used, but there is no convincingly documented evidence of efficacy. Some case series have reported success using psoralen and UVA light (local or whole body), but there have been reports of high relapse rate when treatment is discontinued. Retrospective reviews have suggested that the response is no better than that expected from the natural history.[159–161] The deleterious long-term effects of phototherapy-induced premature skin aging and photocarcinogenesis argue against this treatment option, especially in children.

CONTACT IMMUNOTHERAPY In addition to intralesional glucocorticoid injections, this is the only form of therapy for which efficacy has been convincingly documented. This may be the most effective treatment for patients with extensive alopecia areata, although it is not widely available. Also, there is insufficient comprehensively comparative analysis with alternative treatment options. The patient is sensitized to a potent allergen [usually diphenylcycloprenone (DPCP) or squaric acid dibutylester (SADBE)] and then a solution of DPCP or SADBE is painted on the scalp once weekly. The concentration of DPCP or SADBE is adjusted to induce a mild dermatitis reaction. Published response rates vary widely (9 percent to 85 percent),[5,162] but clinical experience suggests that approximately 30 percent of patients with extensive alopecia areata achieve a cosmetically worthwhile response after 6 months of treatment. Continuous or intermittent treatment is needed to maintain the response in most patients. Alopecia totalis/universalis is less likely to respond to contact immunotherapy, and it is unclear whether patients with rapidly progressive disease profit.

Risks include severe dermatitis, urticaria, and pigmentary abnormalities including vitiligo (an important consideration in racially pigmented skin). Sensitization of health care workers and relatives handling the immunogen is also a significant hazard. Contact immunotherapy has been in use since the early 1980s, and no long-term side effects have been reported.

COSMETIC MEASURES Female patients with extensive alopecia areata often choose to wear a wig or hairpiece. Hair weaves can give good results if sufficient hair remains, although they are expensive to maintain. Locks of Love (http://www.locksoflove.org) is an organization that collects human hair and provides hairpieces to financially disadvantaged children younger than age 18 years with alopecia areata and other chronic forms of alopecia. Wigs are generally less successful in men where other hair styles, such as shaving the scalp, are often a more acceptable approach. Temporary tattooing can be helpful for loss of eyebrows.

NON-SCARRING HAIR LOSS: PRODUCTION DECLINE

Triangular (Temporal) Alopecia

Triangular alopecia may be congenital but usually appears in childhood as a focal patch of hair loss at or just behind the frontotemporal hairline. The hair loss either may be complete or fine vellus hairs may remain.[46,163] The underlying scalp is normal. The hair loss may be uni- or bilateral (Fig. 86-14). Histologically, the affected area shows a transition from terminal to vellus hair. The alopecia is usually persistent. Hair transplants are a reasonable approach. Congenital triangular alopecia may occur within families as a paradominant trait.[164]

Hypotrichosis Simplex

Hypotrichosis simplex, an autosomal dominant disorder, is characterized by progressive global loss of scalp hair

▲ **FIGURE 86-14** Triangular alopecia.

▲ **FIGURE 86-15** Hypotrichosis simplex in a 35-year-old woman.

from early/mid childhood onward. Both sexes are equally affected. The eyebrows and body hair are unaffected and there are no associated features. The pathogenesis has not been studied, but may involve a process of follicular miniaturization resembling pattern hair loss. A mutation in the gene for the adhesion protein corneodesmosin has been reported in some families with hypotrichosis simplex (Fig. 86-15).[165,166]

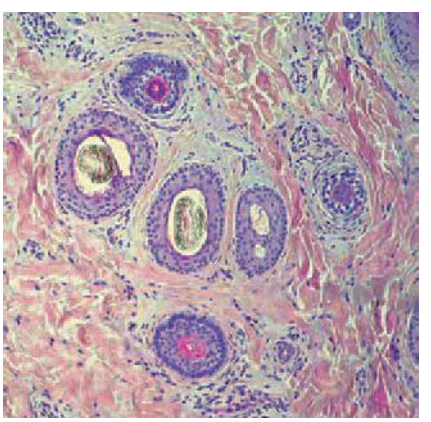
Pattern Hair Loss

Pattern hair loss is by far the most common type of hair loss in both sexes. Male pattern hair loss (also known as *male androgenetic alopecia, male balding*) is an androgen-dependent, genetically determined trait. Female pattern hair loss has also been termed *androgenetic alopecia*, in the belief that it is the same entity as in men, but the requirement for androgens is less clearcut than in men and the distribution of hair loss is generally different.[167,168] However, in both men and women, pattern hair loss is characterized by a progressive decline in the duration of anagen, an increase in the duration of telogen, and miniaturization of scalp hair follicles, indicating a final common pathway of follicular regression (Fig. 86-16).[169]

Pattern hair loss is a biologically normal trait. Nevertheless, the high value our societies place on maintaining a full head of hair means that loss of hair can have a significant adverse effect on quality of life. Both sexes are affected though, in general, the impairment of psychosocial well-being is more frequent and more severe in women.

EPIDEMIOLOGY 1 I R Almost all Caucasian men develop some recession of the hair line in the frontotemporal region following puberty. More advanced balding may start at any time after puberty and its frequency and severity in the population increase with advancing age.[170] Approximately 80 percent of men have some degree of balding by the age of 70 years, and approximately 50 percent show Norwood-Hamilton VI/VII balding (Fig. 86-17). The frequency has been reported to be lower in African American men.[171] Although it is generally thought that the prevalence of androgenetic alopecia in Asian men is much lower than in Caucasians, it is probably higher than often suspected.[172] Interestingly, in Finnish men aged 63 years androgenetic alopecia was significantly associated with insulin-linked disturbances, such as hypertension and diabetes,[173] and patients with a large prostate reportedly show a higher prevalence of androgenetic alopecia.[174,175] In a recent autopsy study, baldness (as well as hair growth in the external auditory canal) were positively associated with coronary artery disease and sudden cardiac death, which revives the long-standing controversial debate of whether and how balding and cardiovascular disease are associated.[176,177]

; SQI R Female pattern hair loss is less common than male balding but shows a similar age-related increase in population frequency and severity. Similar to male balding, the onset may be as early as the peripubertal period but in the great majority it is later. By the age of 30 years, 2 percent to 5 percent of Caucasian women show some thinning of their scalp hair rising to nearly 40 percent at age 70 years.[167,178] Although there is a popular view that late-onset female pattern hair loss is related in some way to post-menopausal changes, this is not apparent from the published epidemiologic data. Similar to male pattern baldness, female pattern hair loss may be associated with coronary artery disease, at least in women under the age of 55 years.[179] Female pattern hair loss is less common in Asian women.[180]



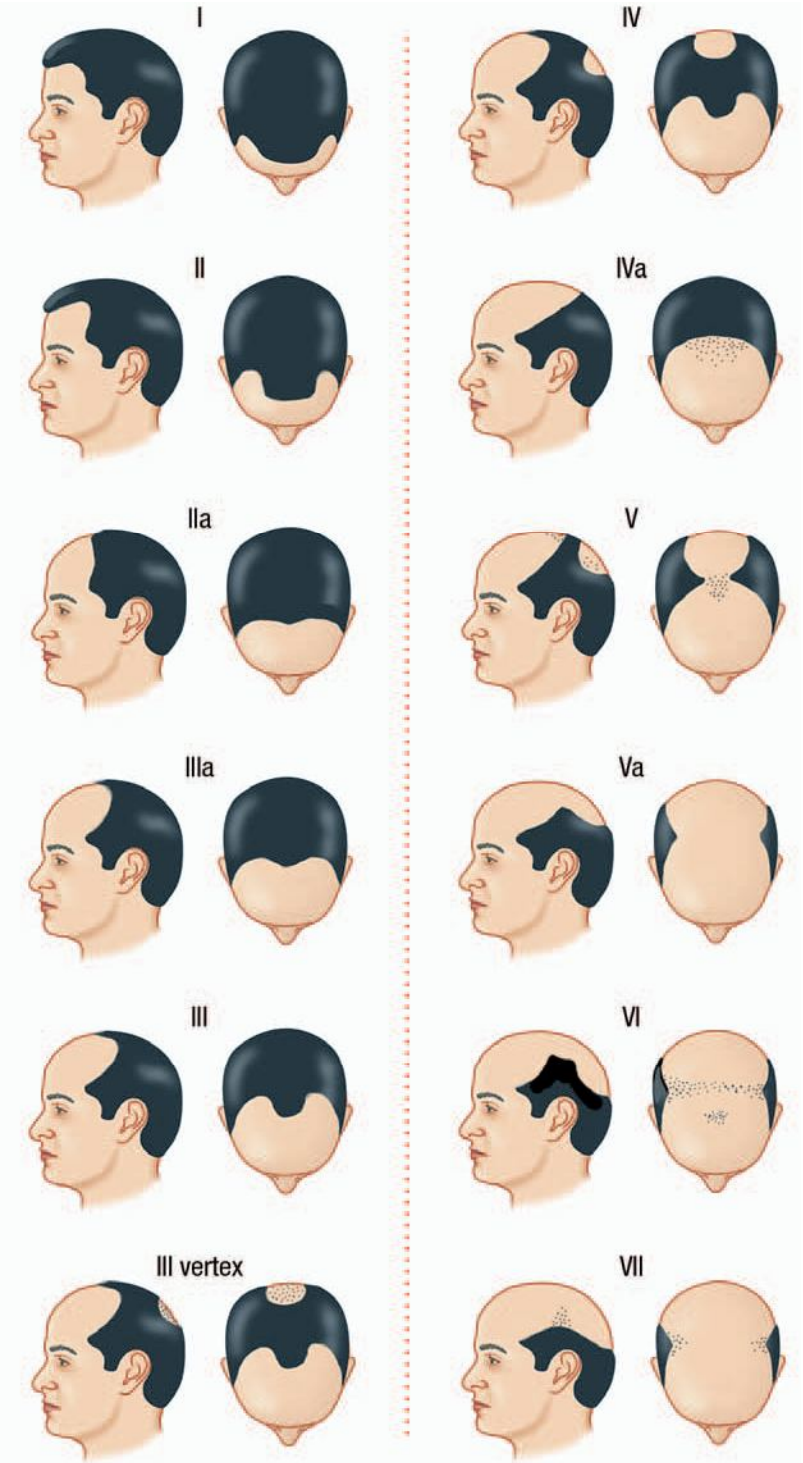
▲ **FIGURE 86-16** Histology of female pattern hair loss. There are two terminal and three vellus follicles in this field of a biopsy from female pattern hair loss.

ETIOLOGY 1 I R Male balding is undoubtedly an androgen-dependent trait. Men castrated before puberty do not develop balding unless subsequently treated with testosterone.[181] Balding also does not occur in XY individuals who fail to express androgen receptors due to a mutation in the androgen receptor gene (complete androgen insensitivity syndrome), despite male levels of circulating testosterone.[182] Although testosterone is the major circulating androgen in men, the balding process is driven by its metabolite dihydrotestosterone, which has greater affinity and avidity for the androgen receptor.[183]

Although testosterone is necessary for its development, it has long been recognized that male balding runs in families, and it is clear that a genetic predisposition is also required. Twin studies show a high level of concordance in monozygotic twins (80 percent to 90 percent),[187] and there is a higher frequency of balding in the fathers of bald men than in the fathers of non-bald men.[188] Osborn proposed that male balding is an autosomal dominant trait,[189] but more recent evaluation of the published data suggests that it has a polygenic basis.[190] Three studies have shown an association between male balding and variant regions in the androgen receptor gene.[191–193] However, this does not explain the paternal influence on male balding, as the locus for the androgen receptor gene is on the X chromosome and is therefore inherited exclusively from the mother.

Recent experimental evidence suggests that, in androgen-sensitive hair follicles, hair growth-inhibitory secreted factors (e.g., transforming growth factor-β) released from androgen-stimulated fibroblasts of the follicular dermal papilla may be at least one key factor in mediating hair growth inhibition and hair follicle miniaturization, at least in male pattern balding.[194–196]

; SQI R Scalp hair loss is a feature of hyperandrogenism in women and rapidly progressive pattern hair loss, particularly when accompanied by other signs of androgen excess such as hirsutism, amenorrhoea, and a raised circulating testosterone level, should prompt a search for an androgen-secreting tumor. Some studies,[197,198] though not all,[199] have reported that, as a group, women with slowly progressive female pattern hair loss show modest elevations of cir-



▲ **FIGURE 86-17** Hamilton-Norwood classification of pattern hair loss in men. (From Olsen EA: Female pattern hair loss. . %Q%GEH(IVQEXS45:S70, 2001.)

culating androgen levels and an increased frequency of polycystic ovaries.[200] Many women with pattern hair loss do not exhibit other biochemical or clinical signs of androgen excess, however, and do not respond to anti-androgen treatment, suggesting that androgens do not play a role.[201] No genetic loci associated with female pattern hair loss have yet been identified.

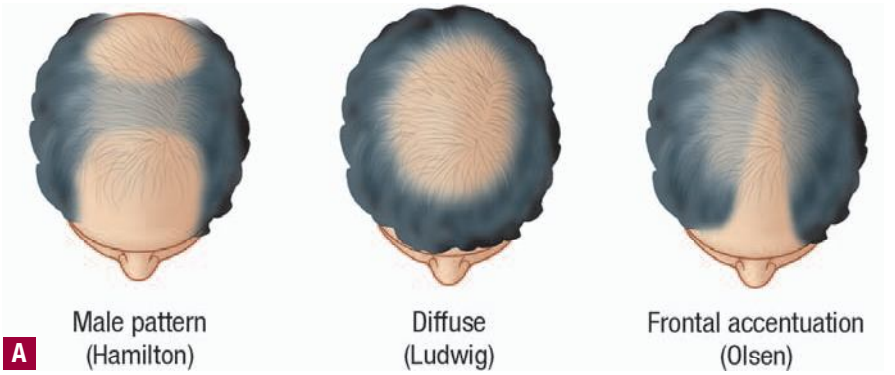
CLINICAL FEATURES Clinical diagnosis, based on male or female pattern recognition, is usually very straightforward. However, hyperprolactinemia may mimic androgenetic alopecia,[199,203,204] and androgenic alopecia due to hyperandrogenism must be distinguished from classic androgenetic alopecia.[7] In addition, a female pattern of hair loss may be seen in males, and vice versa.

1IR The two major features of male pattern hair loss are recession of the frontal hair line and balding of the scalp vertex. Eventually, hair loss may coalesce leaving a rim of normal hair growth at the sides and back of the scalp. The changes that occur during the progression of male balding were first classified by Hamilton,[205] to be later modified by Norwood.[170] Nevertheless, male balding is a continuum rather than a series of distinct stages and individual patterns can vary quite widely (see Fig. 86-17). Hairs within the balding areas may become progressively shorter and finer in caliber, eventually disappearing completely, or show a more diffuse reduction in hair density with maintenance of normal hair diameter in the remaining hairs. In a small proportion of Caucasian men (less than 5 percent), balding assumes a more diffuse distribution over the crown and frontal scalp, with retention of the frontal hair line, resembling female pattern hair loss. This pattern is more common in Asian men.[180]

; SQIR Female pattern hair loss is usually a more diffuse process than male balding. Typically, there is a reduction in hair density involving the crown and frontal scalp, with maintenance of the frontal hair line (Fig. 86-18).[206] There may be miniaturized hairs in the frontotemporal region but deep recession of a well-demarcated hair line is uncommon. Unlike men, the parietal regions may also be involved. Female pattern hair loss may present with excessive hair shedding and loss of hair volume, before there is an obvious reduction in hair density. Differentiation from chronic telogen effluvium can be difficult. In such cases, the diagnosis may be established by the presence of a high proportion of miniaturized follicles on biopsy. A small proportion of women display a "male" pattern of hair loss. It should be emphasized that the distribution of hair loss in women is not a reliable guide to androgen status.

Investigations are probably unnecessary in men and in most women with typical pattern hair loss. However, if the hair loss is diffuse and not localized to typical patterns, it is appropriate to check thyroid stimulating hormone and iron in men on an iron-deficient diet or in whom blood loss could be an issue. Authorities generally recommend the following tests for women with pattern hair loss:

- Serum ferritin (a measure of iron stores): The role of low iron stores in



▲ **FIGURE 86-18** Pattern hair loss in women. **A.** Different phenotypic expressions. **B.** Characteristic frontal accentuation (widened hair part).

female pattern hair loss is uncertain, but there is some evidence that women with serum ferritin less than 40 ™g/L respond poorly to anti-androgen treatment.[207] In women with chronic disease in whom ferritin levels may be elevated due to inflammation, iron and total iron binding capacity should be investigated. Of note, iron-containing medications (including vitamins) should be discontinued for these measurements.

- Thyroid-stimulating hormone: Hair loss is traditionally regarded as a feature of thyroid deficiency although there are few formal published data.[208]
- Serum androgens: The majority of women with female pattern hair loss have no clinical or biochemical evidence of androgen excess.[197] However, screening laboratory testing should be considered, especially in women with concomitant evidence of hirsutism, moderate to severe adult acne, acanthosis nigricans, irregular menses, and/or galactorrhea. Screening studies, at a minimum, should include free and/or total testosterone with or without dehydroepiandrosterone sulfate. Patients with raised serum testosterone levels should be referred for specialist endocrinologic evaluation[7] to consider the presence of a tumor or endocrinologic disorder, such as congenital adrenal hyperplasia.

MANAGEMENT Broadly speaking, patients presenting with pattern hair loss fall into three overlapping groups—those who wish to be reassured that their hair loss is not a manifestation of a serious underlying disease, those who are concerned by it and wish to be treated (Box 86-2), and those with a body dysmorphic disorder. The latter group is important to identify as these patients are unlikely to be satisfied with treatments aimed at restoring hair growth and involvement of other health care professionals, such as a clinical psychologist, may be needed.[1,209] Treatments for pattern hair loss are available, but patients should be counseled that none will restore hair growth to its prepubertal density and that, although some recovery of hair growth is possible, the main aim, at least for medical treatments, is to prevent further progression (see Box 86-2).

1 I R Two medical treatments, TMS and oral finasteride, are licensed for the treatment of male pattern hair loss,[3,7,186] and can be used in combination. A trial of at least 6 months of therapy is needed to assess efficacy, and treatment must be continued to sustain the response.

Box 86-2

Treatment of Androgenetic Alopecia

- Caution against unrealistic expectations; primary goal is to halt progression.
- Male pattern hair loss
  - 5% topical minoxidil solution or foam twice daily.
  - Oral finasteride, 1 mg daily.
  - Combination of the above: Use for at least 6 mo to assess response, and continue treatment to maintain response.
  - Surgery (e.g., hair transplantation). Most useful for restoring frontal hair loss.
- Female pattern hair loss
  - 2%–5% topical minoxidil solution twice daily.
  - Topical 17β-estradiol (e.g., estradiol benzoate, 20–25 mg/mL isopropanol).
  - Oral anti-androgens (spironolactone, cyproterone acetate).
  - Combination of the above: Use for at least 6 mo to assess response, and continue treatment to maintain response.
  - Maintain serum ferritin > 40 ™g/L.
  - Hair transplantation in selected cases.

MINOXIDIL. Clinical trials using a variety of endpoints, including hair counts, hair weight, and global photography, have shown that up to 60 percent of men show improvement in vertex balding using 5 percent TMS with a mean increase in hair density of 10 percent to 12 percent. The response rates with 2 percent TMS are lower.[211] Treatment has to be continued to maintain the response, and any hair gained is lost within 4 to 6 months of stopping treatment.[3] Minoxidil is not effective in treating frontotemporal recession. Minoxidil lotion occasionally causes scalp irritation, most commonly due to the propylene glycol in the vehicle.

FINASTERIDE. Finasteride is an inhibitor of type 2 5α-reductase. Taken orally in a dose of 1 mg daily it prevents the progression of hair loss in most men and, after 2 years of treatment, approximately two-thirds show some improvement in hair growth.[186] In an extended trial, men taking finasteride subsequently showed some loss of hair after 5 years of treatment, but hair loss progressed more rapidly in untreated men.[212] There is a marginally higher frequency of sexually related problems, such as impotence, in men taking finasteride, but otherwise it is generally well-tolerated. Any positive benefit is lost within 12 months if treatment is discontinued. It is unclear how exactly finasteride exerts its beneficial effects in those patients that respond to treatment. One recent study suggests that the reversal of apparent "hair loss" by finasteride reflects some kind of reactivation of "hypotrophic" terminal hair follicles on the basis of faster re-entry into and longer duration of anagen, but not a genuine vellus-to–terminal hair conversion.[213] Despite the absence of formal clinical studies on the efficacy of this combination, topical minoxidil and systemic finasteride are often combined

in clinical practice. A combination of 5α-reductase 1 and 2 inhibition may be beneficial in the treatment of male pattern hair loss.[214]

SURGERY. A variety of surgical techniques have been developed for treating male pattern hair loss, of which hair transplantation is the most widely used.[7,215] All involve redistributing terminal hair to the balding areas so the number of terminal hairs remains the same. In skilled hands, and with careful patient selection, good cosmetic results can be obtained. Surgery is the only treatment that can improve hair coverage on totally bald scalp, and quickly restore hair.[215] Surgery is most effective for restoring frontal hair loss (see Chap. 250).

; SQI R As with male pattern hair loss, a trial of at least 6 months of therapy is needed to assess efficacy, and treatment must be continued to sustain the response. Combinations of agents may be used.

MINOXIDIL. Clinical trials of topical minoxidil solution in female pattern hair loss have reported a mean increase in hair density of 10 percent to 18 percent. One large trial found no significant difference in response to the 2 percent and 5 percent formulations, although there was a trend toward superiority of the higher concentration.[216] At present, only the 2 percent formulation is licensed for women by the U.S. Food and Drug Administration. As in men, a better response is obtained when treatment is used at an early stage of hair loss. Continued treatment is necessary to maintain the response.

ANTI-ANDROGENS. Anti-androgens have been widely used to treat female pattern hair loss, but there is little clinical trial evidence to demonstrate efficacy and none is licensed for this indication. One controlled trial showed a small response to cyproterone acetate but only in those women with clinical evidence of androgen excess.[217] Uncontrolled studies of cyproterone acetate and spironolactone have reported benefit in some patients.[207,218] Generally, 100 to 200 mg/day of spironolactone is needed for response. Potentially fertile women should take contraceptive measures during antiandrogen treatment because of the risk of feminizing a male fetus.

FINASTERIDE. The final verdict on whether or not systemic finasteride may also be a treatment option in post-menopausal women with androgenetic alopecia is still out.[219] A controlled trial of finasteride in post-menopausal women did not demonstrate efficacy,[220] although small case series have reported improvement in hair growth in women with hyperandrogenism[221] and in younger women.[222] Potentially fertile women should take contraceptive measures during treatment with finasteride because of the risk of feminizing a male fetus.

TOPICAL ESTROGENS. Even though convincing clinical trials in support of topical estrogens, a long-practiced, empirical treatment regime for female androgenetic alopecia, are still lacking, topical 17β-estradiol (e.g., estradiolbenzoate, 20 to 25 mg in 70 percent isopronol) is frequently used to counteract androgenetic alopecia-related telogen effluvium in these patients.[5] Notably, estradiol prolongs the duration of anagen, at least in human scalp hair follicle organ culture.[223,224]

SURGERY. Surgical treatment of pattern hair loss is less widely used in women because of the usual diffuse nature of the condition and often poor hair quality in the donor area. However, good results can be obtained in selected cases, particularly in those women with pronounced frontal loss and good hair density in the occipital (donor) region (see Chap 257).[7]

TRAUMATIC HAIR LOSS

Exogenous trauma may cause hair loss, either temporary or permanent, by several different mechanisms, including follicular destruction, hair breakage, and changes in hair follicle cycling.

Pressure Alopecia

There are numerous reports of localized hair loss, usually affecting the occipital scalp, after prolonged surgery or ventilation. The hair loss may be permanent and is presumably due to ischemia from pressure injury.[225,226] In neonates with a history of a capus succedaneum, a "halo scalp ring" may occur, characterized by an annular alopecia that presents as a circumferential ring around the scalp from pressure necrosis; hair loss may be permanent.

Trichotillomania

Trichotillomania (Greek, hair pulling madness) manifests as a compulsive desire or habit to pull out the hair. It occurs in 0.6 percent to 3.4 percent of adults.[227] In young children, trichotillomania is usually a habit akin to thumb sucking, and most recover spontaneously. In teenagers and adults, though, trichotillomania is a more serious and often intractable psychiatric problem. Childhood trichotillomania is more common in boys, but in the adult form, women outnumber men 7:1. This cause of focal scalp hair loss is classified as an impulse control disorder,[228,230,231] and several different underlying psychopathologies can underlie this clinical sign.[229–231]

The clinical presentation is usually quite distinctive, with a confluence of very short sparse hairs within an otherwise normal area of the scalp (Fig. 86-19A,B). Microscopic examination of the ends of cut or plucked hairs generally reveals either the tapered tips of newly regrowing anagen hairs or bluntly broken hairs. (A hair pull here is usually negative because the telogen hairs have generally all been dislodged). The most difficult differential diagnosis is from alopecia areata,[234] but the absence of complete hair loss within affected sites and the firmly anchored nature of broken hairs usually permits the distinction to be made. Where doubt remains, a scalp biopsy can be diagnostic, showing the characteristic increase in the number of catagen hairs (rarely seen in biopsies of normal scalp), trichomalacia, and melanin within the follicular canal secondary to traumatic hair removal and the absence or sparsity of a perifollicular inflammatory infiltrate.[235,236] A vertically oriented hair shaft split, which contains proteinaceous material and erythrocytes ("hamburger sign") has been proposed as an additional, novel histologic pointer to trichotillomania.[237]

Treatment of these patients is difficult. In children, the habit can often be broken by mere acknowledgement of the problem or behavior modification. Adolescents and adults with this condition present a more challenging problem. In those patients who admit to pulling their hair cognitive behavioral therapy is probably the most effective form of treatment, although there is a high failure rate.[238,239] Psychotropic drugs, such as clomipramine or sertraline, may also help. The combination of behavioral therapy (habit reversal training) and medication may be more efficacious in the treatment of trichotillomania than either approach alone.[240] Patients who deny the self-inflicted nature of their

▲ **FIGURE 86-19** Trichotillomania. **A.** Bizarre pattern of localized hair loss in a boy. **B.** Extensive hair loss in a woman.

hair loss usually refuse referral to a psychiatrist or clinical psychologist.

Traction Alopecia

Traction alopecia is caused by inadvertent prolonged traction on the scalp by the physical pressure of hair styling (e.g., pony tail, tight braids, foam rollers, etc.; Fig. 86-20). There is often a cultural element, such as braiding in African American girls[241] or the "topknot" in Sikh boys.[242] The distribution of hair loss reflects that of maximal traction, but is most commonly seen at the scalp margins. Although potentially reversible in its early stages, loss of hair follicles leads to permanent hair loss if the traction is unrelenting over months to years.[243,244]

Tinea Capitis (See Chap. 188)

Tinea capitis is a very common cause of hair breakage or loss, particularly in children. It typically presents with patchy hair loss associated with inflammation of the affected scalp. The degree of inflammation varies from severe pyodermatous swellings (kerion) to barely detectable. It may also present as noninflammatory "black dot ring-worm" presentation, with broken hairs filling, but not projecting from, follicular orifices (see eFig. 86-20.1 in on-line edition).

Treatment of tinea capitis must be by the systemic route, and contacts must be sought and treated to prevent re-infection (see Chaps. 188 and 233).[247]

PRIMARY OR ACQUIRED HAIR SHAFT ABNORMALITIES

Acquired localized trichorrhexis nodosa may be seen in hair that is subject to repetitive rubbing, such as with lichen simplex chronicus or trichotillomania (see the section Trichotillomania). It may also present in focal areas secondary to trauma from chemical or heat processing of hair. Acquired pili torti may present as a focal patch of fragile hair. This is usually secondary to trauma or some underlying, potentially scarring scalp abnormality.[51] Hypervitaminosis in patients with anorexia nervosa or retinoids has also been associated with acquired pili torti.[248] Bubble hair is a recently recognized and very distinctive abnormality of the hair shaft and is characterized by rows of bubbles seen microscopically within localized areas of brittle hair.[250,251] Exposure to prolonged high temperatures from curling irons or hair dryers applied to wet or damp hair are the usual causative factors, and the defect is completely reversible.

◀ **FIGURE 86-20** Traction alopecia.

Unruly Hair

WOOLLY HAIR NEVUS Woolly hair nevus is a non-hereditary focal condition that usually appears within the first 2 years of life but can occur as late as adolescence.[252] Fifty percent of cases have an associated epidermal, verrucous, or pigmented nevus, although not necessarily immediately under the affected hair.[51] There may be associated ocular abnormalities, such as persistent papillary membrane or retinal abnormality. Spontaneous improvement in the hair may occur with age. Both woolly hair and ulerythema ophryogenes have been associated with Noonan syndrome and cardiofaciocutaneous syndrome (see Chap. 85) so that the presence of woolly hair also raises several genodermatoses as differential diagnosis.[253]

ACQUIRED PROGRESSIVE KINKING Acquired progressive kinking has been primarily reported in postpubescent males with androgenetic alopecia.[254] It presents with gradual curling and darkening of the frontal, temporal, auricular, and vertex hairs. Microscopically, affected hairs show kinks and twists, with or without longitudinal grooving.[255]

Abnormality of Cycling

ALOPECIA AREATA Alopecia areata most frequently presents as focal hair loss (see the previous section Alopecia Areata).

SYPHILIS (See Chap. 200) Hair loss may be one or the sole cutaneous manifestation of secondary syphilis.[256] This may present as a patchy "moth-eaten" alopecia (alopecia areolaris) or as generalized thin-

◀ **FIGURE 86-21** Alopecia of secondary syphilis.

ning (Fig. 86-21). If this clinical picture is seen in children, congenital syphilis is to be considered.[257] A scalp biopsy may show either a superficial and deep perivascular mixed lymphocytic/macrophage/plasma cell infiltrate, a peribulbar perifollicular lymphocytic infiltrate mimicking alopecia areata, or a noninflammatory telogen effluvium picture.[258,259] Serologic testing should be positive, and treatment with appropriate antibiotics reverses the hair loss.

Scalp Conditions Associated with Focal Hair Loss

Most eczematous conditions of the scalp do not cause hair loss, the exceptions being pityriasis amiantacea, severe scalp psoriasis or seborrheic dermatitis, scalp involvement with dermatomyositis, and malignancies such as cutaneous T-cell lymphoma or Langerhans cell histiocytosis. In pityriasis amiantacea, thick, tenaciously adherent scale infiltrates and surrounds the base of a group of scalp hairs (Fig. 86-22).[260] The condition may mimic psoriasis clinically, but, in contrast to psoriasis, the hair in involved areas is dislodged on attempts to physically remove the scale. Removal of the scale in this manner can lead to scarring alopecia. The condition usually presents in children, is best treated with the combination of keratolytics and topical corticosteroids, and usually improves with age. Pityriasis amiantacea represents a particular reaction pattern of the scalp to various inflammatory scalp diseases, most frequently seborrheic dermatitis or psoriasis. However, tinea capitis must be excluded in every case, and topical antibiotics can be a helpful adjuvant therapy if recalcitrant.[261]

CICATRICIAL ALOPECIA (DESTRUCTION OF THE FOLLICLE)

The term *cicatricial* or *scarring alopecia* implies the potential of permanent destruction of the hair follicle,[262] most likely as a result of irreversible damage to epithelial hair follicle stem cells in the region of the bulge.[263,264] Clinically, there is effacement of follicular orifices, always in a patchy or focal distribution. A biopsy is confirmative, showing replacement of follicles with fibrotic stellae and either fibrosis or hyalization of surrounding collagen.[265–268] Although some cases of cicatricial alopecia are due to physical causes (e.g., pressure or chronic traction) or to the hair follicle being secondarily involved in a destructive process (e.g., "kerion" fungal infection, necrotizing zoster, metastatic/primary neoplasm) or as the result of a developmental defect (aplasia cutis congenita), most patients seeking medical attention have a primary cicatricial alopecia. Although these conditions have a common endpoint (irreversible alopecia), they have varied clinical and histologic features and virtually no therapies (Table 86-7) are able to turn the process completely off.

A new classification system has been proposed by the North American Hair Research Society to identify and evaluate significant differences among these entities.[271] The primary cicatricial alopecias are presented in keeping with this classification system (see Table 86-7).[262] The power of routine histology to allow definitive distinctions between various types of cicatricial alopecia is disputed, but direct immunofluorescence may help to make such distinctions.[272,273]

Primary Cicatricial Alopecia

LUPUS ERYTHEMATOSUS (See Chap. 156) Chronic cutaneous lupus erythematosus may present in the scalp, usually with erythema, atrophy, and variable hypopigmentation and/or follicular plugging (see eFig. 86-22.1 in on-line edition).

LICHEN PLANOPILARIS Areas of active alopecia in lichen planopilaris are clinically distinguished by perifollicular erythema and/or a violaceous discoloration of the scalp. Keratotic follicular papules may be evident. Evidence of lichen planus may be present elsewhere, and this should be sought to help confirm the diagnosis (see Chap. 26).

+Ya La Q 0IMXP 7] RHNSQI Graham-Little syndrome is characterized by lichen planus–like lesions and a follicular "spines"/keratosis pilaris-like picture that develop in areas of alopecia on the scalp, eyebrows, axillary, and pubic areas (see Chap. 26).[265]

*\SRa P*NA\SVWK %ESTI GaM *Frontal fibrosing alopecia* is a term given to the frontotemporal hairline recession and eyebrow loss in post-menopausal women that is associated with perifollicular erythema, especially along the hairline.[277] Scalp biopsy is largely indistinguishable from lichen planopilaris, although frontal fibrosing alopecia may show more prominent apoptosis and less inflammation than lichen planopilaris, along with spared interfollicular epidermis.[276] Topi-

◀ **FIGURE 86-22** Pityriasis amiantacea. Note area of patchy alopecia after manual removal of adherent scale.

TABLE 86-7
Primary Cicatricial Alopecias: Salient Clinical Features and Treatment Regimens[a]

	Clinical			
Entity	**Epidemiology**	**Scalp**	**Non-Scalp**	**Therapy[a,b]**
Lymphocytic[c]				
Discoid lupus erythematosus	Women > men	Symptomatic, erythematous scaly plaques with follicular plugs; telangiectases, atrophy and depigmentation with time; activity in center of alopecic patch	May be present; rule out systemic lupus erythematosus	• Topical ± intralesional steroid • Hydroxychloroquine, prednisone; topical tacrolimus, tazarotene, imiquimod • Isotretinoin
LPP (classic)	Women > men	Pruritic, multifocal, or central alopecic patches with follicular hyperkeratosis and erythema at hair-bearing margin	May be present (especially as lichen ruber mucosae)	• Topical ± intralesional steroid • Oral retinoid, prednisone, hydroxychloroquine, oral cyclosporine
Frontal fibrosing alopecia	Post-menopausal women	Frontotemporal recession often with classic LPP at hair-bearing margin	May be present (eyebrows)	• Topical ± intralesional steroid • Anti-androgens, finasteride
Graham-Little syndrome	Adults	Patches with follicular hyperkeratosis	May be present (non-scarring in axillae, pubic area)	See text
Graft-versus-host disease	See Chap. 28	Usually presenting like LPP, hyperpigmentation may be present	See Chap. 28	• Prednisone • Calcineurin inhibitors • Topical steroid, psoralen and ultraviolet A light, etretinate
Pseudopelade of Brocq	Adults	Asymptomatic, noninflamed ivory-white or flesh-colored small oval-round confetti-like, reticulate, or large, irregular patches, ± atrophy	Rarely present (beard); separate entity, or end-stage variant of LPP?	• Topical ± intralesional steroid • Prednisone, hydroxychloroquine, isotretinoin
Central centrifugal cicatricial alopecia (previously also known as [illegible] in African Americans)	Especially black women	Central scalp; noninflamed late stage; flesh-colored symmetric patch	Absent	• Cease traumatic/chemical hair-care practices • Topical steroid + oral tetracycline
Keratosis follicularis spinulosa decalvans	Onset in childhood	Patchy, follicular hyperkeratosis ± perifollicular erythema	Present; photophobia, keratosis pilaris	• Topical and intralesional steroid • Isotretinoin
Alopecia mucinosa	All ages	Polymorphous disease (e.g., erythematous plaques with patulous ostia): alopecia areata-like, diffuse, or complete alopecia	May be present; rule out malignancy, because this is a classic presenting symptom of cutaneous T-cell lymphoma (see Chap. 146)	For primary form: • Topical steroid, intralesional steroid • Minocycline, isotretinoin • Phototherapy
Neutrophilic[c]				
Folliculitis decalvans	Adults	Usually central scalp; grouped follicular pustules, miliary abscesses at hair-bearing margin	Generally absent; may represent scalp variant of hidradenitis suppurativa/acne inversa (see http://www.hs-foundation.org)	• Antibiotic ± topical steroid • Rifampin + second antibiotic • Fusidic acid + zinc • Isotretinoin
Mixed				
Acne keloidalis	Especially black men	Occipital scalp; firm red-brown papules, papulopustules, nodules and keloidal plaques	Absent	• Intralesional steroid ± antibiotics • Excision (plaque form), cryotherapy, isotretinoin
Erosive pustular dermatosis	Especially elderly women	Asymptomatic, crusted purulent plaque	Absent	• Topical steroid, calcipotriol • Zinc

LPP = lichen planopilaris.
[a]Therapy of cicatricial alopecia is severely hampered by the paucity of evidence-based medicine. Most treatment regimes are based on anecdotal reports or small study series; double-blind, randomized, placebo-controlled, prospective studies in a sufficiently large cohort of patients are virtually non-existent.
[b]The main aim of treatment is to prevent progression, and patients should be advised that significant recovery of hair growth is unlikely.
[c]Histologically, it is relatively easy to distinguish the lymphocytic and neutrophilic groups of cicatricial. However, currently it is exceedingly difficult, if not impossible, to distinguish clinically distinct primary cicatricial alopecias within these two groups.
Adapted from Ross EK, Tan E, Shapiro J: Update on primary cicatricial alopecias. [illegible] 53:1, 2005.

▲ **FIGURE 86-23** Frontal fibrosing alopecia.

cal and intralesional steroids, topical and systemic retinoids, and hormone replacement therapy do not prevent the hair loss progression (Fig. 86-23).

PSEUDOPELADE OF BROCQ In clinical terms, pseudopelade of Brocq[278] implies flesh- to pink-colored, irregularly shaped alopecia that may begin in a "moth-eaten" or characteristic "footprints-in-the-snow" pattern with eventual coalescence into larger patches of alopecia (Fig. 86-24).[43,278] There is no follicular erythema or hyperkeratosis, yet the disease may progress inexorably. There has been considerable debate as to the specificity of this diagnosis versus an assignation of the term to describe all noninflammatory scarring alopecias, including the end-stage of a variety of initially inflammatory conditions. Histologically, the lesions are characterized by a perifollicular and perivascular lymphocytic infiltrate primarily at the level of the follicular infundibulum, loss of sebaceous epithelium, and fibrotic streams into the subcutis without interface or follicular plugging changes.[279] Elastin stains may distinguish pseudopelade (persistent elastic fibers around the midshaft of the follicle) from lichen planopilaris and lupus erythematosus (loss of elastic fibers in this location).[280] Direct immunofluorescence is negative in the majority of cases. However, in general, the histology is similar, if not identical, to that of lichen planopilaris.[273] It is unclear whether any treatment helps.

Other Forms of Scarring Alopecia

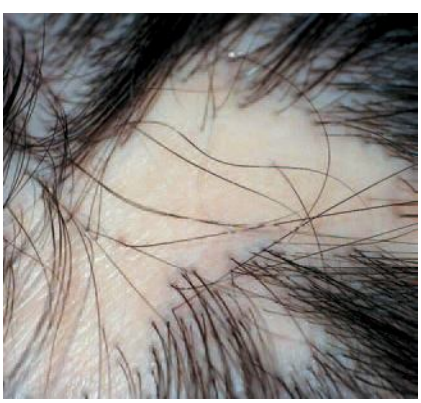
Central centrifugal cicatricial alopecia (CCCA) is a form of cicatricial alopecia that affects adults of African orgin.[43,271] This condition has also been called *hot comb alopecia* or *follicular degeneration syndrome*. This starts at the crown or midline vertex and spreads slowly in a centrifugal fashion. Inflammation has been reported more commonly in affected men than in affected women.[282] Histologically, the earliest and most distinctive change is premature desquamation of the inner root sheath with later changes through the outer root sheath (including migration of the hair shaft), a mononuclear infiltrate primarily at the isthmus, and, finally, loss of the follicular epithelium and replacement with fibrous tissue.[282] Although tight braiding, hot combs, and hair straightening agents are often invoked as causative or at least contributory factors and their use discouraged in CCCA, this has not been definitely proven. The distribution of CCCA overlaps that of pattern hair loss but the sex distribution is tremendously skewed toward women.

Alopecia mucinosa , also known as *follicular mucinosis*, generally presents as erythematous, alopecic papules, plaques, or flat patches on the scalp and face.[267] Biopsy reveals prominent follicular, epithelial, and sebaceous gland mucin, and perifollicular lymphohistiocytic infiltrate, which may be associated with follicular lymphocyte exocytosis, without concentric lamellar fibrosis.[265,267,283] In adults, alopecia mucinosa almost invariably represents follicular mycosis fungoides (see Chap. 146).[283] It is controversial whether a self-limited variant exists in children.

Keratosis follicularis spinulosa decalvans is a rare, usually X-linked disorder with the gene located at Xp22.13–p22.2 (see Chap. 85).[284,285]

Folliculitis decalvans is an inflammatory disease characterized by pustular folliculitis leading to scarring hair loss. Surviving hairs may group so that multiple hairs are seen emerging from a single follicular orifice (tufted folliculitis) (Fig. 86-25). *Staphylococcus aureus* is usually cultured from these pustules, but whether this is a primary or secondary process is unclear. Histologically, early lesions show an acute suppurative folliculitis with neutrophils and eosinophils, later mixed with lymphocytes and histiocytes.[265,266] Loss of sebaceous epithelium and perifollicular fibrosis is common.[265] Systemic antibiotics, particularly in combination with rifampin, systemic and/or topical steroids, and systemic retinoids may also be helpful.[289]

Dissecting folliculitis or perifolliculitis capitis abscedens et suffodiens is another inflammatory condition of the scalp that can lead to scarring alopecia. African Americans are particularly affected. This condition begins with deep inflammatory nodules, primarily over the occiput, that progress to coalescing regions of boggy scalp (Fig. 86-26). Sinus tracts may form and dislodge purulent material. As in folliculitis decalvans, *S. aureus* is the most common bacterial isolate. Biopsy of early lesions shows follicular plugging and suppurative follicular or perifollicular abscesses with a mixed inflammatory infiltrate of neutrophils, lymphocytes, plasma cells, or eosinophils.[265–267] Later, foreign-body giant cells, granulation tissue, and, finally, scarring with sinus tracts occur. Control is difficult to attain, but small case series have reported success with oral isotretinoin, systemic antibiotics (using similar regimens to folliculitis decalvans), systemic steroids, and dap-



▲ **FIGURE 86-24** Pseudopelade of Brocq.

◀ **FIGURE 86-25** Folliculitis decalvans.

◀ **FIGURE 86-26** Dissecting folliculitis.

sone.[262,290] Surgical incision and drainage, excision with grafting, and/or x-ray epilation are occasionally used for refractory cases.

Acne keloidalis (nuchae) is a destructive scarring folliculitis that occurs mostly on the occipital scalp of African Americans, primarily men (Fig. 86-27). The clinically distinctive lesions begin as follicular pustules and papules and progress to persistent firm papules or coalesce into hairless keloid-like plaques.[291] On histopathologic examination of an early lesion, there is follicular dilatation and a mixed peri-infundibular infiltrate that goes into follicular rupture and foreign body granulomas, loss of sebaceous glands, and lamellar fibroplasia. Mild forms of the disease may be treated with topical or intralesional corticosteroids, or systemic antibiotics, and/or cryotherapy. Surgical excision of the affected skin the most effective treatment for severe acne keloidalis.[262]

The primary lesion in acne necrotica is a pruritic or painful erythematous follicular-based papule that develops central necrosis and crusting and heals with a varioliform scar.[292,293] The lesions are concentrated on the nose, forehead, and anterior scalp, but may spread, primarily to the trunk. The course is chronic. Histologically, acne necrotica is a lymphocytic necrotizing folliculitis.[292] Possible treatments include systemic antibiotics and oral isotretinoin.[262,292]

Erosive pustular dermatosis of the scalp is predominantly a disease of the elderly, mainly women, although pediatric cases do occur.[294] It presents as chronic boggy crusted plaque on the scalp overlying exudative erosions and pustules, eventually leading to scarring alopecia (Fig. 86-28).[295,296] A history of preceding trauma may be obtained,[294,297] and there are several reports of onset after treatment for actinic keratoses.[262] On biopsy, there is a lymphoplasmacytic infiltrate with or without foreign body giant cells and pilosebaceous atrophy. Multiple organisms, both bacterial and fungal, have been cultured, but these probably represent secondary colonization; patients do not generally respond to antibacterial or antifungal drugs. No single treatment is uniformly successful, but potent topical steroids, topical tacrolimus,[298] or isotretinoin may be helpful.[297]

Secondary Cicatricial Alopecia

Cicatricial alopecia may present as a hereditary or development problem, alone or as part of a syndrome. Examples of the latter are Conradi-Hünermann chondrodysplasia punctata; incontinentia pigmenti; ankyloblepharon, ectodermal defect, cleft lip or palate syndrome; Hallermann-Streiff syndrome; and generalized atrophic benign epidermolysis bullosa.[46]

Congenital Cicatricial Alopecia

The most common congenital cicatricial alopecia is aplasia cutis congenita, which is the congenital focal absence of epidermis with or without absence of other layers of the skin.[46] Hair follicles in the involved areas are variably affected. The condition may present at birth as an ulceration, crust, scar, or parchment-like membrane (see Chap. 106).

EXCESS HAIR

Hirsutism refers to hair growth in women in areas of the body where hair growth is under androgen control and in which normally only postpubescent males have terminal hair growth. These areas include the moustache, beard, chest, escutcheon, and inner thigh.

Hypertrichosis specifically refers to hair density or length beyond the accepted limits of normal for a particular age, race, or sex. The excess hair may be generalized or localized and may consist of lanugo, vellus, or terminal hair.

Hirsutism

EPIDEMIOLOGY What constitutes significant hirsutism is difficult to define, as it depends on a variety of cultural and racial factors, media-driven perceptions of normality, and the perceptions of the individual physician and patient.[299] Not surprisingly, therefore, estimates of the frequency of hirsutism in the female populations have varied widely. In Lon-

◀ **FIGURE 86-28** Pustular dermatosis of the scalp.

don, 1.2 percent of women were significantly hirsute.[300] Other studies have reported frequencies of up to 18 percent.[299] The frequency and distribution of female androgen-dependent hair growth also varies with age; terminal hair growth in the pubic and axillary regions declines with age, whereas facial hair growth increases. These difficulties have led to the use of the patient-determined term *unwanted hair* to influence therapeutic decision making. Nevertheless, the physician may still have to make a value judgment as to when patient concerns really represent a body dysmorphic disorder, rather than a problem solvable by hair removal.

PATHOGENESIS Terminal hair growth in a "male" pattern is undoubtedly due to the effect of androgens, and reflects the conversion of vellus to terminal hair follicles. In many women, hirsutism is associated with raised levels of circulating androgens (54 percent in one series).[301] However, in some, androgen levels are within the normal range, suggesting in these individuals that hair growth is especially sensitive to androgen stimulation. Recent evidence suggests that testosterone increases 5α-reductase gene expression in dermal papillae from lower abdominal skin of women with hirsutism; theoretically, this may raise the dihydrotestosterone-generating potency of these hair follicles.[302] Also, only certain 5α-reductase type 1 haplotypes are reportedly associated with hirsutism,[303] which further raises the question of whether inherited, constitutive abnormalities in intrafollicular dihydrotestosterone synthesis are an important element in the pathogenesis of hirsutism. Other clinical features of hyperandrogenism include oligo- or amenorrhea, sub- or infertility, acne, acanthosis nigricans, and female pattern hair loss to frank virilization with male pattern balding and clitoromegaly.[304] Table 86-8 lists causes of hyperandrogenism, of which polycystic ovary syndrome is by far the most common.[304,305]

INVESTIGATION Whether and how to investigate hirsute women depends on a number of factors, including the presence of clinical features of increased androgen production, the duration of the history, and the concerns of the patient. In fertile women with normal menses and a long history of relatively mild hirsutism, it is debatable whether investigation is necessary at all. In women with moderate to severe hirsutism, particularly when accompanied by other signs of androgen excess, further evaluation is warranted (Table 86-9). Women with hyperprolactinemia may have an increase in functional androgens through adrenal overproduction and through a decrease in sex hormone–binding globulin caused by a diminution of ovarian estrogen production.[306]

TABLE 86-8
Hirsutism

- Androgen-secreting tumors
  - Adrenal
    - Adenoma
    - Adenocarcinoma (rare)
    - Ectopic adrenocorticotropic hormone–secreting tumor (rare)
  - Ovarian
    - Gonadal stromal tumor
    - Thecoma
    - Lipoid tumor

Functional androgen excess

- Adrenal enzyme deficiencies (congenital adrenal hyperplasia)
  - Early onset 21-hydroxylase deficiency
  - Late-onset 21-hydropxylase deficiency
  - 11β-hydroxylase deficiency
  - 3β-ol dehydrogenase deficiency
- Cushing syndrome
- Polycystic ovarian disease
  - With or without adrenal contribution
  - Hyperthecosis
- "Idiopathic" hirsutism
- Medication/drug use

Hughes CL: Hirsutism, in (MSVH VWSJ, EVM+VS[X. (MKRSVMERH8VEQI Rédited by Olsen EA. New York, McGraw-Hill, 1994, p 344, Table 14-2.

TABLE 86-9
Recommended Investigation for Hirsutism

- Serum testosterone (if > 200 ng/mL, exclude androgen-secreting tumor)
- Serum-free testosterone and dehydroepiandrosterone (more sensitive; most women with moderately elevated androgen levels have polycystic ovarian syndrome)
- 17-hydroxyprogesterone (raised level suggests congenital adrenal hyperplasia; confirm diagnosis by repeat measurement after adrenocorticotropic hormone stimulation)
- Serum prolactin (hyperprolactinemia due to macro- or microprolactinoma or treatment with neuroleptic drugs[331]; may have associated menstrual abnormalities, infertility, and galactorrhea)

Box 86-3
Treatment of Hirsutism

Remove existing terminal hair and prevent further vellus-to-terminal transformation

- Temporary hair removal
  - Shaving, plucking, depilatory creams
  - Topical eflornithine (slows growth; does not remove hair)
- (Potentially) permanent hair removal
  - Electroepilation[332]
  - Laser hair removal[307]
- Anti-androgen measures
  - Weight loss
  - Oral anti-androgens (spironolactone, cyproterone acetate)
  - Oral contraceptives
  - Finasteride

wanted terminal hair, and the reduction of the androgen drive toward further vellus-terminal transformation. The latter approach (e.g., using anti-androgens) may also help to reduce hair growth but, on its own, is unlikely to eliminate it (Box 86-3). Shaving, plucking, and use of depilatory creams are temporary means of hair removal that can be irritating and painful. The topically applied inhibitor of ornithine decarboxylase, eflornithine 13.9 percent, is approved for the reduction of unwanted facial hair in women when applied twice daily.

Laser epilation is less permanent than often suspected, is most effective when applied repetitively, and patients should be discouraged from unrealistic expectations. The mechanism of laser epilation is the selective photothermolysis of melanized hair through absorption of light energy.[307] The combination of the topically applied eflornithine with laser therapy may decrease the growth after hair removal.[308]

Weight loss may be helpful in obese patients because obesity increases free testosterone levels by reducing sex hormone–binding hormone and contributes to insulin resistance.

There are marginal differences in efficacy between systemically administered agents, but all generally take 6 to 12 months for sufficient miniaturization of terminal hairs to be clinically significant. These include oral anti-androgens (such as spironolactone, 100 to 200 mg daily) or cyproterone acetate,[309–312] oral contraceptives, and finasteride.[309,313] Oral contraceptives inhibit androgen synthesis by inhibiting the output of gonadotropins and are most effective if combined with anti-androgens. Treatment of congenital adrenal hyperplasia may also be accom-

plished through the use of low-dose dexamethasone.[314] Hyperprolactinemia may be treated directly with either medical (bromocriptine) or surgical treatment of the hyperprolactinoma, possibly combined with an anti-androgen.

Hypertrichosis

Congenital hypertrichosis lanuginosa presents as a confluent, generalized overgrowth of silvery blonde to gray lanugo hair at birth or in early infancy.[315] It is rare (1 in 1 billion) and thought to occur as an autosomal dominant trait with variable expressivity. In most cases, other than possibly anomalous dental eruptions, children are otherwise healthy. The hair may persist, increase, or decrease with age.[316–318]

There are several other congenital disorders associated with generalized hypertrichosis, but none that are so evenly distributed as congenital hypertrichosis lanuginosa (Table 86-10).[43] Patients with the autosomal dominant Ambras syndrome or hypertrichosis universalis congenita present with much longer, thicker hair, with accentuation over the entire face, ears, and shoulders.[319–321] Associated facial dysmorphism and dental anomalies are common. Members of the five-generation family described with congenital generalized hypertrichosis also have excess terminal hair on the face and upper body, more severe in men than women in keeping with the X-linked dominant inheritance.[318,322] Patients with the autosomal dominant (rarely autosomal recessive) gingival fibromatosis frequently have hypertrichosis, mostly on the face, eyebrows, limbs, and upper back, along with seizures and oligophrenia.[43,315] Hypertrichosis may be delayed until puberty, although gingival fibromatosis in this situation usually appears with the emergence of the primary, versus secondary, teeth.

ACQUIRED GENERALIZED HYPERTRICHOSIS

There are few more ominous signs in dermatology than the onset of generalized hypertrichosis without an obvious drug-related explanation. Generalized acquired hypertrichosis lanuginosa almost always signals an underlying malignancy or is a harbinger of one to develop in the near future (Fig. 86-29 and see eFig. 86-29.1 in on-line edition; see Table 86-10 and Chap. 154).[323,324] However, an association with autoimmune hepatitis has also been reported.[325] More frequently, extensive acquired hypertrichosis is a common feature of porphyria cutanea tarda, variegate porphyria, and congenital erythropoietic porphyria (see Chap. 132).

There are several drugs that routinely cause generalized hypertrichosis (see Table 86-10).[43,315] Oral minoxidil, a piperidinopyramidine derivative that is a potassium channel opener and antihypertensive agent when used systemically, causes hypertrichosis in 80 percent of patients, most prominently over the face, shoulders, and extremities.[210] Diazoxide, a benzothiadiazine used primarily in malignant hypertension or idiopathic hypoglycemia of infancy, leads to lanugo-like hypertrichosis of the face, trunk, and extremities in 1 percent to 20 percent of adults but in almost 100 percent of children. Dilantin use leads to terminal hair hypertrichosis in 5 percent to 12 percent of patients, again first over the extremities, trunk, and face. The immunosuppressive immunophilin ligand, cyclosporine A, causes terminal hair hypertrichosis in 40 percent to 95 percent of patients, with a more diffuse distribution of ex-

▲ **FIGURE 86-30** Cyclosporine-related hypertrichosis.

cess hair, but primarily over the upper body (Fig. 86-30).[326–328] Based on findings in the mouse, the underlying mechanism likely reflects premature anagen induction as well as catagen inhibition by cyclosporine A,[133,329] which may contribute to the vellus to terminal hair conversion that leads to hypertrichosis.

LOCALIZED HYPERTRICHOSIS Table 86-11 lists the conditions associated with localized hypertrichosis. These are generally inherited, developmental, or secondary to irritation or trauma.

TREATMENT Removal of the inciting cause should be the prime approach to treatment and usually leads to regression of the hypertrichosis. However, in situations in which this is not possible, one must either help the patient deal psychologically with the physical anomaly and/or use means of either temporarily or permanently removing the hair. The same methods of hair removal described for hirsutism management may be used for hypertrichosis as well, except for the anti-androgenic approaches (see Box 86-3).

CHAPTER 87

Biology of Nails and Nail Disorders

Antonella Tosti
Bianca Maria Piraccini

BIOLOGY OF NAILS

The nail apparatus consists of a horny "dead" product, the nail plate, and four specialized epithelia: the proximal nail fold, the nail matrix, the nail bed, and the hyponychium (Fig. 87-1A). The nail apparatus develops during the ninth embryonic week from the epidermis of the dorsal tip of the digit as a rectangular area, the nail fold, which is delineated by a continuous groove.[1] The proximal border of the nail fold extends downward and proximally into the dermis to form the nail matrix primordium. By the fifteenth week the nail matrix is completely developed and starts to produce the nail plate, which will continue to grow until death. The nail apparatus lies immediately above the periosteum of the distal phalanx. The intimate anatomic relationship between the nail and the bone is responsible for the common occurrence of bone alterations in nail disorders and vice versa. The shape of the distal phalangeal bone also determines the shape and the transverse curvature of the nail.

Fingernails usually present a longitudinal major axis and toenails a transverse major axis. The ratio between length and width is important for the aesthetic appearance of the nails. The size of the nails varies in the different digits. The biggest nail is that of the first toe, which covers approximately 50 percent of the dorsum of the digit.

Nails have numerous functions. Fingernails not only contribute to the pleasing appearance of the hands, but are very important in protecting the distal phalanges and enhancing tactile discrimination and the capacity to pick up small objects. They are also widely used for scratching and grooming and are an efficient natural weapon. Toenails protect the distal toes and contribute to pedal biomechanics.

Nail Plate (See Fig. 87-1A)

The nail plate is a fully keratinized structure that is continuously produced throughout life (see Fig. 87-1B). It results from maturation and keratinization of the nail matrix epithelium and is firmly attached to the nail bed, which partially contributes to its formation. Proximally and laterally the nail plate is surrounded by the nail folds, which cover its proximal third and lateral margins. At the tip of the digit, the nail plate separates from the underlying tissues at the hyponychium. The nail plate is rectangular, translucent, and transparent. It is curved in both the longitudinal and transverse axes, especially in the toes. The nail plate surface is smooth but frequently shows mild longitudinal ridges that increase with aging. The pattern of these ridges can be used for forensic identification. The bottom of the nail plate shows longitudinal ridges that correspond to the rete ridges of the nail bed. The nail plate is homogeneously pink, except for its free edge, which is white. The pink color of the nail plate is due to the nail bed blood vessels.

The proximal part of the fingernails, especially of the thumbs, shows a whitish, opaque, half-moon–shaped area, the lunula, that is the visible portion of the nail matrix. In this area the nail plate attachment to the underlying epithelium is loose. More than 90 percent of fingernails show a thin distal transverse white band, the onychocorneal band, which marks the most distal portion of firm attachment of the nail plate to the nail bed.[2] This area represents an important anatomic barrier against environmental hazards, and its disruption produces nail plate detachment with onycholysis. The onychocorneal band is separated from the nail plate white free edge by a 1.0- to 1.5-mm pink band called the *onychodermal band*.

In transverse sections, the nail plate consists of three portions: dorsal nail plate, intermediate nail plate, and ventral nail plate.[3] The dorsal and the intermediate portions of the nail plate are produced by the nail matrix, whereas its ventral portion is produced by the nail bed. Above the lunula the nail plate is thinner and consists only of the dorsal and intermediate portions. There is a natural line of cleavage between the dorsal and the intermediate nail plate.

The nail plate progressively thickens from its emergence to its distal margin. The mean toenail thickness at the distal margin is 1.65 ± 0.43 mm in men and 1.38 ± 0.20 mm in women. Fingernails are thinner; the mean thickness is 0.6 mm in men and 0.5 mm in women. There is an increase in nail thickness with age, particularly in the first two decades. Nail thickness depends on the length of the nail matrix and nail bed.[4] Thinning of the nails is usually a sign of nail matrix disorders, whereas nail thickening is most commonly a consequence of nail bed disorders.

Proximal Nail Fold (See Fig. 87-1A)

The proximal nail fold is a skinfold that consists of a dorsal and a ventral portion. The dorsal portion is anatomically similar to the skin of the dorsum of the digit but thinner and devoid of pilosebaceous units. The ventral portion, which cannot be seen from the exterior and proximally continues with the germinative matrix, covers approximately one-fourth of the nail plate. It closely adheres to the nail plate surface and keratinizes with a granular layer. The limit between the proximal nail fold and the nail matrix can be histologically established at the site of disappearance of the granular layer.

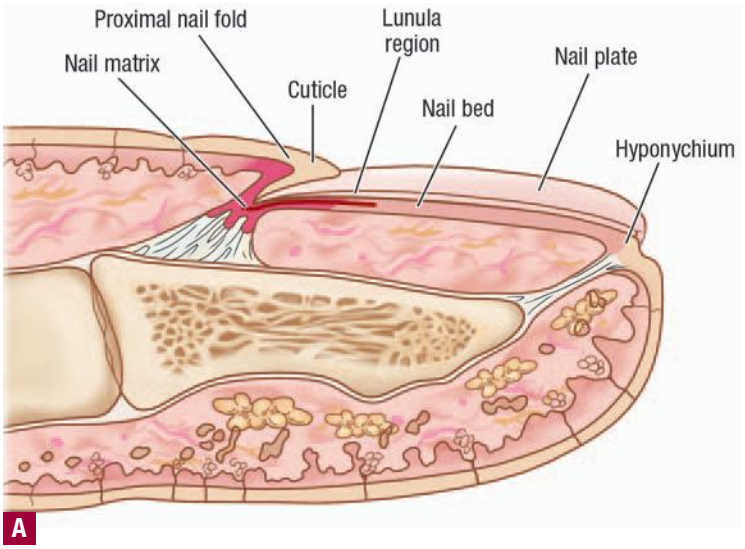
The horny layer of the proximal nail fold forms the cuticle, which is firmly attached to the superficial nail plate and prevents the separation of the plate from the nail fold. The integrity of the cuticle is essential for maintaining the homeostasis of this region.

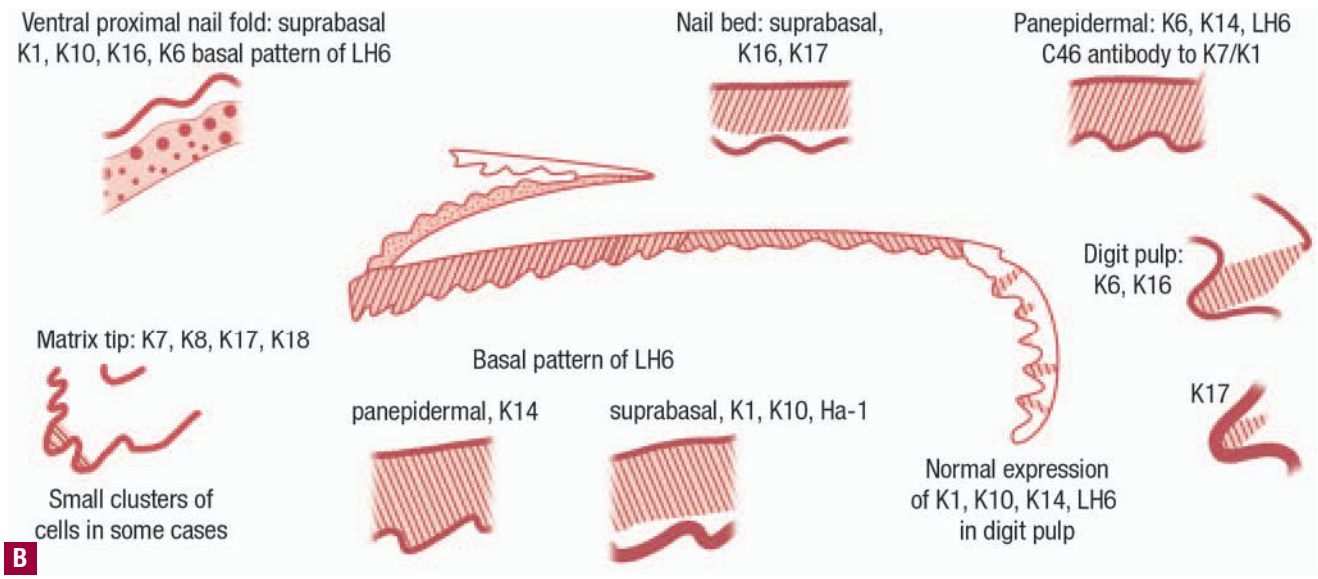
The dermis of the proximal nail fold contains numerous capillaries that run parallel to the surface of the skin and may easily be observed in vivo by capillary microscopy (Fig. 87-2). This permits the observation of both the arterial and the venous limbs of the capillaries, which are arranged in parallel rows and appear as fine regular loops with a small space between the afferent and efferent limbs. The morphology of proximal nail fold capillaries is typically altered in connective tissue diseases.[5–8]

Nail Matrix (See Fig. 87-1A)

The nail matrix is a specialized epithelial structure that lies above the mid portion of the distal phalanx. After elevation of the proximal nail fold, the matrix appears as a distally convex crescent with its lateral horns extending proximally and laterally.

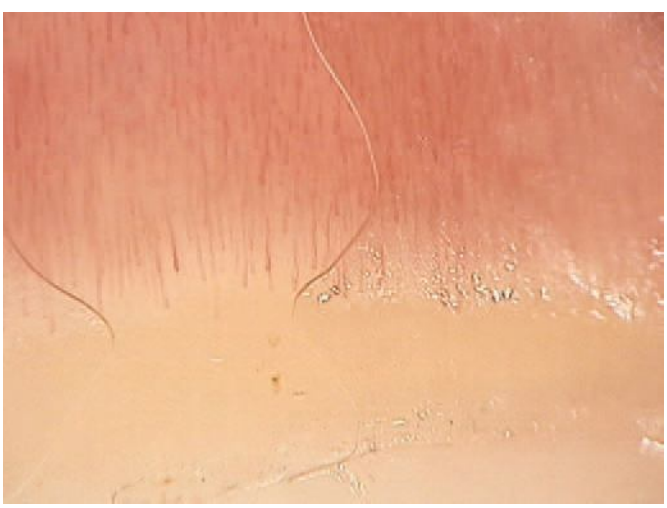
In longitudinal sections the matrix has a wedge-shaped appearance and consists of a proximal (dorsal) and a distal (ventral) portion. Nail matrix keratinocytes divide in the basal cell layer and keratinize in the absence of a granular zone. The site of keratinization (keratogenous zone) of nail matrix ony-





◀ **FIGURE 87-1** **A.** Diagrammatic drawing of a normal nail. **B.** Keratin gene expression at different locations within the nail. (From De Berker D et al: Keratin expression in the normal nail unit: Markers of regional differentiation. &V. (I VQEXSP **142**:89, 2000, with permission.)

chocytes can be clearly distinguished in histologic sections as an eosinophilic area where cells show fragmentation of their nuclei and condensation of their cytoplasm.[1] In this area, nuclear fragments are destroyed by deoxyribonuclease and ribonuclease enzymes. In some conditions nuclear fragments may persist within the intermediate nail plate, producing leukonychial spots. These, however, frequently disappear before reaching the nail free edge, due to the persistence of active DNA and RNA lytic enzymes within the horny nail plate.



▲ **FIGURE 87-2** Capillary microscopy of the proximal nail fold showing the longitudinally oriented capillary loops.

Maturation and differentiation of nail matrix keratinocytes do not follow a vertical axis, as in the epidermis, but occur along a diagonal axis that is distally oriented. For this reason, keratinization of the proximal nail matrix cells produces the dorsal nail plate and keratinization of the distal nail matrix cells produces the intermediate nail plate.

In some fingers the distal matrix is not completely covered by the proximal nail fold but is visible through the nail plate as a white half-moon–shaped area, the lunula. The white color of the lunula results from two main anatomic factors: (1) the keratogenous zone of the distal matrix contains nuclear fragments that cause light diffraction; (2) nail matrix

capillaries are less visible than nail bed capillaries because of the relative thickness of the nail matrix epithelium.[9]

NAIL MATRIX KERATINOCYTES (See Fig. 87-1B) The nail matrix cells are able to synthesize both "soft" or skin-type and "hard" or hair-type keratins.[10–12] Evaluation of keratin expression in the different constituents of the nail apparatus showed that the nail matrix is the sole site of expression of hard keratin proteins, particularly Ha1 keratin.[13] Data indicate that fibroblasts derived from the nail matrix may induce hard keratin expression in non–nail matrix keratinocytes.[14]

MELANOCYTES (See Chap. 70) Nail matrix melanocytes are usually quiescent and therefore not detectable in pathologic sections. They possess the key enzymes that are necessary for melanin production, however, and may become activated by a large number of physiologic and pathologic conditions.[15] Nail matrix melanocyte activation produces diffuse or banded nail pigmentation and is more common in blacks and Japanese than in Caucasians. DOPA-negative (inactive) melanocytes are sparsely present in the nail matrix and in the nail bed.[16] DOPA-positive, activated melanocytes are especially seen in the distal nail matrix, where they are frequently arranged in small clusters among the suprabasal layers of the nail matrix epithelium.[17]

LANGERHANS CELLS (See Chap. 10) Langerhans cells are more numerous in the proximal than in the distal nail matrix. As in normal epidermis, Langerhans cells are predominantly found in the suprabasal layers. However, they may occasionally be seen within the basal layer of the nail matrix epithelium.

MERKEL CELLS The presence of Merkel cells in the nail matrix has been demonstrated. Their density is possibly influenced by age, with these cells being more numerous in fetus than in adult nails.[18]

Nail Bed (See Fig. 87-1A)

The nail bed extends from the distal margin of the lunula to the onychodermal band and is completely visible through the nail plate. The nail bed epithelium is so adherent to the nail plate that it remains attached to the undersurface of the nail when the latter is avulsed.

The nail bed epithelium is thin and consists of two to five cell layers. Its rete ridges, which are longitudinally oriented, interdigitate with the underlying dermal ridges in a "tongue-and-groove"–like fashion. Nail bed keratinization produces a thin horny layer that forms the ventral nail plate. Nail bed contribution to nail plate formation corresponds to approximately one-fifth of the terminal nail thickness and mass.[19] In pathologic sections, the ventral nail plate is easily distinguishable because of its light eosinophilic appearance. Nail bed keratinization is not associated with the formation of a granular layer. This may appear, however, when the nail bed becomes exposed after nail avulsion.[1]

Hyponychium

The hyponychium marks the anatomic area between the nail bed and the distal groove, where the nail plate detaches from the dorsal digit (see Fig. 87-1A). Its anatomic structure is similar to that of plantar and volar skin, and keratinization occurs through the formation of a granular layer. The horny layer of the hyponychium partially accumulates under the nail plate free margin. The hyponychium is normally covered by the distal nail plate, but it may become visible in nail biters.

Basement Membrane Zone

The antigenic structure of the basement membrane zone of the nail is identical to that of the epidermis, and there are no differences in the antigenic composition of the basement membrane zone in the different portions of the nail apparatus.[16,20] This may explain the involvement of the nails in conditions characterized by mutations of basement membrane–associated genes as well as in autoimmune skin diseases involving the basement membrane zone antigens.[21]

Dermis (See Fig. 87-1A)

The nail apparatus is devoid of subcutaneous tissue, and its dermis does not contain pilosebaceous units. The arrangement of the rete ridges varies in the different portions of the nail apparatus. The dermis beneath the proximal nail matrix consists of condensed connective tissue that forms a tendon-like structure connecting the matrix to the periosteum of the proximal phalangeal bone (posterior ligament). A small amount of subdermal fat tissue is present close to the periosteum of the base of the phalanx.[22] The close connection between the lateral horns and the periosteum is possibly responsible for the nail plate's lateral convexity. The rete ridges of the dermis underneath the nail matrix are characteristically long and root-like in shape. The dermis under the distal matrix consists of a loose network of connective tissue containing numerous blood vessels and rare glomus bodies.

The dermis of the nail bed has a unique arrangement with longitudinal grooves and ridges that run from the lunula to the hyponychium.[1] The longitudinal orientation of the capillary vessels within the nail bed grooves explains the linear pattern of nail bed hemorrhages (splinter hemorrhages). The nail bed dermis contains abundant connective tissue networks with connective tissue bundles radiating to the phalangeal periosteum. It contains numerous glomus bodies.

Blood and Nerve Supply

The nail apparatus has an abundant blood supply provided by the lateral digital arteries (see Fig. 87-2). These run along the sides of the digits and produce both branches that supply the matrix and the proximal nail fold and arches that supply the matrix and the nail bed. The nail matrix, therefore, has two different sources of blood supply. The nail bed is richly supplied (10 to 20 cm^2) by incapsulated neurovascular structures containing one to four arteriovenous anastomoses and nerve endings. These glomus bodies may be involved in the regulation of the blood supply to the digits in cold weather. The cutaneous sensory nerves, which originate from the dorsal branches of the paired digital nerves, run parallel to the digital vessels.

Chemical Properties (See Fig. 87-1B)

The nail plate, like hair, consists mainly of low-sulfur filamentous proteins (keratins) embedded in an amorphous matrix composed of high-sulfur proteins rich in cysteine. Other nail constituents include water, lipids, and trace elements. Nail keratins consist of 80 percent to 90 percent hard hair-type keratins and 10 percent to 20 percent soft skin-type keratins. Hard keratins have been identified as the acidic 44K/46K and basic 56K/60K keratins. Soft keratins have been identified as the 50K/58K and 48K/56K keratin pairs.[23] Keratin filaments have a transverse orientation that is parallel to the nail surface. This explains why the nail plate is more

susceptible to transverse fractures than to longitudinal fractures. Specific keratins are expressed only in some compartments of the nail unit; for instance, K6a and K6b, K16, and K17 are not expressed in the nail matrix.[13,24,25] Mutations of the genes encoding for these keratins are associated with nail thickening due to nail bed hyperproliferation, as is seen in pachyonychia congenita (PC).[26,27]

Under normal conditions the water content of the nail plate is 18 percent, and most of the water is in the intermediate nail plate.[28] This may vary significantly, however, because of the high porosity of the nail plate, which allows it to be rapidly hydrated and dehydrated. Dehydration is faster when the nails are kept long. When the water content decreases below 18 percent, the nail becomes brittle; when it increases above 30 percent, it becomes opaque and soft.[29]

The nail contains less than 5 percent lipids, mainly cholesterol; the nail plate lipid content is under hormonal control and decreases after menopause.[30] The nail plate also contains traces of several inorganic elements, particularly iron, zinc, and calcium. These, however, do not contribute to nail hardness.

Physical Properties

The nail plate is hard, strong, and flexible. The hardness and strength of the nail plate are due to its high content of hard keratins and cysteine-rich high-sulfur proteins, whereas its flexibility depends on its water content and increases with nail plate hydration.[31] The double curvature of the nail plate along its longitudinal and transverse axes enhances nail plate resistance to mechanical stress.[32]

The physical properties of the nail also depend on the arrangement and adhesion of onychocytes in the different portions of the nail plate, as well as on the orientation of the keratin filaments within the nail plate onychocytes.[32] At the ultrastructural level, the corneocytes of the dorsal nail plate are flat, with their shorter diameter perpendicular to the nail plate surface. The average sizes of these cells are 34 μm in length, 64 μm in width, and 2.2 μm in height.[33] Cell adhesion is strong. This portion of the nail is responsible for nail plate hardness and sharpness. The onychocytes of the intermediate nail plate show multiple interdigitations of their cell membranes. The average dimensions of these cells are 40 μm in length, 53 μm in width, and 5.5 μm in height. Cell adhesion is provided by desmosomes. This part of the nail plate is responsible for nail pliability and elasticity. The ventral nail plate is thin and consists of soft keratins. It provides adhesion to the underlying nail bed.

Nail Growth

The nail plate grows continuously throughout life. Fingernails grow faster than toenails, with a mean growth of 3 mm/month for fingernails and 1 mm/month for toenails. Complete replacement of a fingernail requires 100 to 180 days (6 months). When the nail plate is extracted, it is approximately 40 days before the new fingernail first emerges from the proximal nail fold. After a further 120 days it will reach the fingertip.[29] The total regeneration time for a toenail is 12 to 18 months. As a consequence of the slow nail growth rate, diseases of the nail matrix only become evident a considerable time after their onset and require a long time to disappear after treatment.

Nail growth rate varies among different individuals and among the different digits of the same individual. It depends on the turnover rate of the nail matrix cells and is influenced by several physiologic and pathologic conditions. Nail growth rate is slow at birth, increases slightly during childhood, and usually reaches its maximum between the second and the third decades of life. It sharply decreases after the age of 50 years.[34]

Conditions that have been associated with a slow growth rate include systemic illness, malnutrition, peripheral vascular or neurologic diseases, and treatment with antimitotic drugs. Nails affected by onychomycosis frequently exhibit a slow growth rate. An arrest of nail growth is a typical feature of yellow nail syndrome. Conditions that have been associated with accelerated nail growth include pregnancy, finger trauma, psoriasis, and treatment with oral retinoids or itraconazole. Accelerated nail growth may cause longitudinal ridging of the nail plate (nail beading).

Due to their slow growth rate, the nails may provide information on pathologic conditions that have occurred up to several months before the time of observation. Drugs, chemicals, and biologic substances accumulate in nails, where they can be detected and measured. Advantages of analyzing nail samples include the ease and non-invasiveness of their collection, the small sample size required for analysis, and the ease of storage at room temperature. The nail of the big toe is the best site for investigation because of its size and slow growth rate.[35]

NAIL SIGNS AS A FUNCTION OF THE SITE OF PATHOLOGY[1,29] (Table 87-1)

Beau's Lines and Onychomadesis (Nail Shedding)

Beau's lines result from a temporary arrest of proximal nail matrix proliferation and appear as transverse grooves, often deeper in the central nail plate, that move distally with nail growth. Onychomadesis also results from a temporary arrest in nail matrix activity, and the proximal nail plate is detached from the proximal nail fold by a whole-thickness sulcus. Causes of onychomadesis are the same as those for Beau's lines but are more severe (Table 87-2). Multiple Beau's lines or onychomadesis in the same nail indicates repetitive insults. The time of the insult leading to Beau's lines can be dated by measuring the distance of the groove from the proximal nail fold. Local trauma, such as from manicures or onychotillomania, or related to local cutaneous disease, particularly dermatitis, periungual erythema, and paronychia, are causes of Beau's

TABLE 87-1

  - Kawasaki syndrome
  - Peripheral ischemia

lines (Fig. 87-3). Beau's lines at the same levels in several nails suggest a systemic cause. Most common among these are drugs (especially chemotherapy), high fever, viral illness,[36,37] surgery, and peripheral ischemia. Onychomadesis in children often relates to recent coxsackievirus infection.[36]

Pitting

Pits result from small areas of abnormal keratinization of the proximal nail matrix that produce foci of parakeratotic cells in the superficial nail plate. They appear as small punctate depressions of the superficial nail plate, which progress distally and often become more evident with nail growth (Fig. 87-4). Deep and irregularly distributed pits are seen in psoriasis and atopic dermatitis; geometric and superficial pits are typical of alopecia areata (see Chaps. 18, 14, and 86).

▲ **FIGURE 87-3** Beau's lines and toenail onychomadesis due to trauma by footwear.

▲ **FIGURE 87-4** Pitting. Note small punctate depressions of the superficial nail plate. In this patient, the presence of onycholysis surrounded by an erythematous border suggests a diagnosis of psoriasis.

Onychorrhexis (Longitudinal Striations and Fissuring)

Onychorrhexis results from diffuse defective keratinization of the proximal nail matrix. The nail plate is usually thinned and presents multiple longitudinal ridges and fissures. Onychorrhexis is typical of lichen planus (see Chap. 26).

Longitudinal Grooves

Longitudinal grooves are usually single and appear as a longitudinal depression of the nail plate (1 to 2 mm large) due to compression of the nail matrix by tumors of the proximal nail fold (Fig. 87-5).

Trachyonychia

Trachyonychia results from multiple foci of defective keratinization of the proximal nail matrix. The nails are rough due to excessive longitudinal ridging.

True Leukonychia

True leukonychia results from defective keratinization of the distal matrix with persistence of parakeratotic cells in the ventral nail plate. The superficial nail plate is structurally normal, but the nail presents opaque white patches or striae, which often disappear before reaching the distal edge of the nail. Punctate leukonychia is due to microtrauma and is typically seen in the fingernails of children. Striate leukonychia of fingernails is a consequence of aggressive manicure. Total or subtotal leukonychia is usually hereditary (Fig. 87-6).

▲ **FIGURE 87-5** Irregular longitudinal groove of the nail plate due to matrix compression by a myxoid cyst of the proximal nail fold.

Koilonychia

In koilonychia the nail plate is thin and spoon shaped. Koilonychia is physiologic in the toenails of children. In adults it can be a sign of iron deficiency or occupational factors.

Melanonychia[38]

Melanonychia is due to the presence of melanin in the nail plate. It can be caused by activation or proliferation of nail matrix melanocytes. In most cases melanonychia appears as a single or longitudinal brown to black band. Multiple bands of melanonychia are usually due to melanocyte activation, as is seen in darker-skinned individuals, pregnant women, those with inflammatory nail

▲ **FIGURE 87-6** True striate leukonychia.

TABLE 87-3

- Trauma

disorders or Laugier-Huntziker syndrome, those taking certain medications (Table 87-3), and individuals with a variety of systemic disorders, particularly human immunodeficiency virus infection and Addison syndrome. In Laugier-Huntziker syndrome, melanonychia is associated with the presence of lip and/or genital pigmented macules and usually affects several digits; it begins during adolescence[39,40] (see Chap. 73). A single band of melanonychia may be a sign of a nail matrix nevus or melanoma (see Chaps. 122 and 124). Melanonychia affecting the fourth and/or fifth toenail is usually due to trauma. Longitudinal melanonychia of a single nail often deserves biopsy.

Longitudinal Erythronychia[41]

Longitudinal erythronychia reflects a nail bed disorder. A single longitudinal red line extending from the proximal nail to the distal edge is most commonly caused by onychopapilloma or other benign subungual tumors. Multiple bands of longitudinal erythronychia are seen in Darier disease (see Chap. 49).

▲ **FIGURE 87-7** Distal splinter hemorrhages (EXS).

▲ **FIGURE 87-8** Schematic drawing showing pattern of exogenous pigmentation (PJX) and endogenous pigmentation (WKLX).

Onycholysis

Onycholysis is detachment of the nail plate from the nail bed and can be caused by traumatic, inflammatory, infectious, or neoplastic nail bed disorders. See Onycholysis under Environmental Nail Disorders later.

Splinter Hemorrhages

Splinter hemorrhages appear as red to black small thin longitudinal lines under the nail plate. They are more commonly located in the distal nail plate and represent rupture of the longitudinally oriented nail bed capillaries (Fig. 87-7). Causes include trauma and inflammatory nail disorders, such as psoriasis.

Apparent Leukonychia

In apparent leukonychia the nails are pale white due to nail bed discoloration that fades with pressure.

Subungual Hyperkeratosis

Subungual hyperkeratosis is due to inflammatory disorders that cause an abnormal keratinization of the distal nail bed and hyponychium with accumulation of scales under the distal nail plate. The most common causes include psoriasis, onychomycosis, trauma, and atopic dermatitis (see Chaps. 18, 188, and 14).

Paronychia

Paronychia is inflammation of the proximal nail fold and presents as painful periungual erythema, sometimes with associated purulence. Acute paronychia is usually caused by infection (see Infectious Nail Disorders). Chronic paronychia is most commonly due to mechanical or chemical factors. If the periungual area is fluctuant or shows purulence, it should be drained to avoid matrix damage. Topical and/or systemic antibiotics should be administered if bacterial infection is suspected.

Nail Pigmentation

Nail pigmentation is most commonly due to exogenous staining of the nail plate. In this case the proximal margin of the pigmentation follows the shape of the proximal nail fold. Exogenous nail pigmentation is most commonly due to occupational exposures or nail cosmetics. Nail pigmentation due to endogenous causes is rare. The proximal margin of the pigmentation follows the shape of the lunula (Fig. 87-8). Possible causes include drugs, argyria, hemochromatosis, alkaptonuria, and Wilson disease.

HEREDITARY AND CONGENITAL NAIL DISORDERS[42] (Table 87-4)

Ectodermal Dysplasias (See Chap. 143)

Nail changes may be associated with hypotrichosis, hypodontia, and hypohidrosis. Most common are short, thickened, hypoplastic nails.

Epidermolysis Bullosa (See Chap. 60)

In all sub-types of epidermolysis bullosa nail changes are common and may be the first or the only symptom of the disease. Junctional and dermolytic epidermolysis bullosa may produce anonychia.

Pachyonychia Congenita (See Chap. 48)

PC is a group of autosomal dominant disorders characterized by severe nail thickening due to massive nail hyperkeratosis[42] (Table 87-5). Type 1 PC is associated with

TABLE 87-4
Hereditary and Congenital Nail Disorders

Ectodermal dysplasias	• Atrophy/thickening
Epidermolysis bullosa	• Partial or total anonychia • Pachyonychia • Subungual/periungual hemorrhagic blisters

    - Natal teeth
    - Pili torti
    - Hoarseness

mutations of K6a and K16 genes,[43] whereas type 2 PC is caused by mutations of K6b and K17.[44,45] In PC both fingernails and toenails are thickened, yellow-gray, and transversely overcurved with marked subungual hyperkeratosis most notable at the distal portion of the nails (Fig. 87-9). Nail trimming is impossible, because the nails are extremely hard. The abnormalities usually develop during childhood, but a late-onset variety of PC has been described.[46] Focal palmo-plantar keratoderma is associated with the nail changes in 60 percent of patients or may result from mutations without detectable nail changes.[47] Up to 75 percent of patients have oral leukokeratosis; hyperhidrosis of the palms and soles, follicular keratoses, and acral bullae (especially during warmer months) are common. Patients with type 2 PC also tend to have cystic lesions (steatocystoma multiplex, vellus hair cysts), which reflects the expression of K6b and K17 in adnexal structures. The cystic lesions begin during childhood and progressively appear. Coarse or twisted hair, early primary tooth loss, and natal teeth are other occasional features of type 2 PC, reflecting expression of the affected genes in the hair follicle apparatus and teeth.

Nail Patella Syndrome

Nail abnormalities in nail patella syndrome may involve all fingernails or may be limited to the thumbs, which are always the most severely affected digits (Fig. 87-10). Nail hypoplasia is usually more marked in the medial portion of the nail. The shape of the lunula is typically triangular.[42]

Congenital Malalignment of the Hallux

Congenital malalignment of the hallux is the most common cause of ingrowing (ingrown) nails and is usually diagnosed when the child starts to walk. The great toenail shows a lateral deviation that produces embedding of the lateral side of the nail plate. The digit is painful and the toenail often shows Beau's lines and onycholysis (Fig. 87-11). Congenital malalignment may be unilateral or bilateral. Spontaneous improvement may occur, and most children do not have symptoms by the age of 2 years.[48] Inflammation due to lateral ingrowing can be managed by daily massaging of the lateral nail fold with creams containing steroids, antibiotics, and urea. Surgical treatment is invasive and usually not necessary.[49]

▲ **FIGURE 87-10** Nail patella syndrome: nail hypoplasia and triangular lunula.

INFECTIOUS NAIL DISORDERS (Table 87-6)

Acute paronychia is most commonly due to *Staphylococcus aureus* infection and typically affects a child's fingernail. Predisposing factors include nail biting or sucking and occupational traumas. The proximal nail fold is painful, erythematous, and swollen. Pus may be discharged after pressure (see Chap. 177).The differential diagnosis includes herpes simplex virus infection (see Chap.

◀ **FIGURE 87-9** Pachyonychia congenita of the fingernails in an adult (**A**) and of the toenails in a 4-year-old boy (**B**). Note the severe nail thickening and transverse hypercurvature due to compact nail bed hyperkeratosis.

▲ **FIGURE 87-11** Congenital malalignment of the big toenail. The longitudinal axis of the nail is deviated laterally. Note Beau's lines and mild lateral ingrowing.

193) and Hallopeau acrodermatitis (see Chap. 21), both of which have a typical relapsing course. Suspicion of herpes simplex virus infection should arise when the pain intensity is disproportionate to the clinical symptoms and the disease is recurrent. Most commonly, cephalosporins are initiated as therapy. However, any purulent material should be drained if possible and cultured to ensure choice of the optimal antibiotic.

Green Nails

Bacteria are not capable of attacking a healthy nail plate. The Gram-negative bacterium *Pseudomonas aeruginosa* may colonize the dorsal or ventral nail plate under propitious conditions, such as chronic paronychia or onycholysis. The presence of *Pseudomonas* is revealed by a characteristic green-black nail pigmentation due to pyocyanin staining (Fig. 87-12). Topical application of a few drops of diluted bleach or chlorhexidine solution two or three times a day clears the pigmentation in a few weeks. Administration of systemic antibiotics is unnecessary.

▲ **FIGURE 87-12** Onycholysis with green discoloration due to 4WWYH-BQSFEVW colonization.

Onychomycosis[50,51]

For a detailed description of the onychomycoses see Chap. 188. Onychomycosis is a common toenail disease, and its prevalence increases with age.

Clinical features depend on type of nail invasion (Table 87-7). The possibility of mold onychomycosis should be suspected when proximal subungual onychomycosis is associated with periungual inflammation (Fig. 87-13) or when white superficial onychomycosis is severe and involves the entire nail plate (Fig. 87-14). Nondermatophytic onychomycoses are becoming more frequent worldwide and represent a clinical problem, because they usually respond poorly to systemic treatment.

TABLE 87-6

DSO = distal subungual onychomycosis; PSO = proximal subungual onychomycosis.

ONYCHOMYCOSIS AT A GLANCE

- Fifteen percent of the general population and 40 percent of individuals older than 60 years are affected.
- Clinical presentation reflects the route of nail invasion.
- Dermatophytes account for 85 percent of cases, nondermatophytic fungi for 15 percent.
- Infection with human immunodeficiency virus should be suspected with proximal subungual onychomycosis (PSO).
- Mold fungal infection should be suspected when PSO is associated with acute periungual inflammation or when white superficial onychomycosis involves most of the nail plate.
- 'ERHMEsp. are the causative agents only in immunosuppressed individuals.
- Toenails are involved in most cases; tinea pedis is usually associated.
- The cure rate for toenail onychomycosis is approximately 80 percent with the use of systemic antifungals, but recurrences are frequent (up to 20 percent). Mold infections respond poorly to systemic treatment.

ENVIRONMENTAL NAIL DISORDERS

Nail Fragility[52] (Table 87-8)

With nail fragility, the nails are brittle and show distal lamellar splitting (onychoschizia). Several nails are usually affected. The nail plate margin is irregular due to distal splitting. Idiopathic nail fragility usually affects middle-aged women who are exposed to water and chemicals that dehydrate the nail plate. Aging also is associated with increased nail fragility. The risk of nail fragility from trauma is increased by manicures, onychotillomania, and certain occupations, especially those that involve frequent exposure to water and chemicals. Fragile nails can be a feature of several

dermatologic disorders, among them lichen planus, alopecia areata, psoriasis, and onychomycosis. In addition, nutritional deficiency, peripheral neuropathies, peripheral vascular disease, and use of certain medications increase the risk of nail fragility. Management includes protection of the hands by the use of cotton gloves under rubber gloves and frequent application of topical moisturizers. Oral biotin, 5 mg/day, can be helpful.[53]

Chronic Paronychia[54,55]

Chronic paronychia is an inflammatory disorder that almost exclusively involves the fingernails of adult women. Mechanical or chemical trauma damages the cuticle and permits penetration of irritant and allergenic environmental substances, which cause an inflammatory reaction of the proximal nail fold and nail matrix. Secondary colonization with *Candida* sp. and/or bacteria occurs in most cases, causing self-limited episodes of painful acute inflammation (see Chap. 189). Chronic paronychia most commonly affects the first, second, and third fingers of the dominant hand. Clinically the proximal and lateral nail folds show mild erythema and swelling, and the cuticle is absent. The nail plate may show superficial abnormalities and green discoloration due to *Pseudomonas* invasion.

▲ **FIGURE 87-13** Proximal subungual onychomycosis due to %WIVKMRWRMV. Note severe periungual inflammation.

Onycholysis

Idiopathic onycholysis usually affects the fingernails of women and is a consequence of mechanical and chemical damage of the onychodermal band (Table 87-9). The detached nail plate is white due to the presence of air and frequently presents areas of green-brown discoloration due to bacterial colonization. The use of sharp tools to clean the nail plate free margin produces roller coaster onycholysis (manicure onycholysis). Traumatic onycholysis of the fingernails is usually occupational and is more commonly observed in butchers, slaughterhouse workers, chicken processing workers, and workers lifting heavy bags. Traumatic onycholysis of the toenails most frequently affects the big toe, often bilaterally. It is usually a consequence of anatomic abnormalities

▲ **FIGURE 87-14** White superficial onychomycosis due to %WIVKMRWLEZYW with diffuse and deep nail plate invasion.

CHRONIC PARONYCHIA AT A GLANCE

- Occurs most commonly in food handlers and housecleaners.
- Associated with mechanical or chemical cuticle damage.
- Characterized by eczematous inflammation of the proximal nail fold and matrix.
- Secondary colonization by bacteria and yeasts usually occurs.
- First, second, and third digits of the dominant hand are most often affected.
- Management includes protective measures, topical and/or systemic steroids, and topical antimicrobials.
- Systemic antifungals are not effective.

TABLE 87-8

  - Peripheral neuropathies
  - Nutritional deficiencies

IDIOPATHIC ONYCHOLYSIS AT A GLANCE

- Occurs in homemakers and those in certain occupations.
- Caused by mechanical or chemical damage.
- Follows asymptomatic and slowly progressive nail plate detachment.
- Management includes taking protective measures, trimming the onycholytic nail plate, and applying topical antiseptics.

(overlapping of the second toe on the first toe) or poorly fitting shoes. Subungual hematoma is frequently associated. Secondary onycholysis is seen in several dermatologic disorders. When only one nail is affected, it is important to explore the nail bed after cutting the onycholytic nail to rule out a nail tumor. Patients with idiopathic onycholysis should be instructed to keep the nail dry, trim the onycholytic nail plate, and wear cotton gloves under rubber gloves. Application of topical 4 percent thymol in chloroform solution on the exposed nail bed can accelerate cure.

NAIL TUMORS[56]

Tumors of the nail usually affect one digit and are often associated with nail plate furrows or grooves or localized onycholysis. In some situations nail pigmentation is altered.

Benign Tumors

FIBROMA/FIBROKERATOMA Fibroma/fibrokeratoma appears as a nodular or filiform growth that often has a keratotic surface. Most fibromas originate in the proximal nail fold and extend to the nail plate surface, where the tumor presents as a longitudinal furrow or groove (Fig. 87-15). Subungual lesions are uncommon. Tuberous sclerosis should be considered, especially if multiple lesions are present (see Chap. 141).

SUBUNGUAL EXOSTOSIS[57] Subungual exostosis appears as a subungual hard nodule that detaches and lifts the nail plate (Fig. 87-16). The toenails of young adults are usually affected, and a history of trauma is not unusual. Radiography confirms the diagnosis.

MYXOID CYST[58] Myxoid cyst appears as a nodule of the proximal nail fold associated with a longitudinal groove in the correspondent nail plate. Because the cyst often drains spontaneously, the shape of the groove is irregular (see Fig. 87-5). Myxoid cysts usually affect the fingernails of middle-aged women and are associated with osteoarthritis of the interphalangeal joints.

▲ **FIGURE 87-15** Fibrokeratoma of the proximal nail fold. Note the longitudinal groove of the nail plate due to matrix compression.

▲ **FIGURE 87-16** Subungual exostosis.

GLOMUS TUMOR Glomus tumor may hardly be seen, appearing as a small red patch under the nail plate and usually affecting the hand (Fig. 87-17). The minimal clinical appearance is disproportionate to the intense pain, which is usually accentuated by cold and radiates to the limb.

ONYCHOMATRICOMA[59] The clinical presentation of onychomatricoma is typical: the affected nail is thickened, whitish, and overcurved with longitudinal tunnels (hollows), which are evident at the frontal view (Fig. 87-18).

NAIL MATRIX NEVI[60,61] Nail matrix nevi appear as a band of longitudinal melanonychia and are usually diagnosed in childhood (Fig. 87-19). The color and width of the band are variable, and modification of the pigmentation with aging is common. Although the rate of progression of nail matrix nevi to melanoma is probably low, some advise excision of these lesions after puberty.

▲ **FIGURE 87-17** Glomus tumor of the nail bed, appearing as a violaceous subungual patch.

▲ **FIGURE 87-18** Onychomatricoma: nail overcurvature with white longitudinal striations corresponding to nail plate tunnels.

Malignant Tumors

SQUAMOUS CELL CARCINOMA (See Chap. 114) In situ squamous cell carcinoma (Bowen disease) usually manifests in fingernails with a lesion that clinically closely resembles a wart. Associated melanonychia or paronychia may be a diagnostic clue. Squamous cell carcinoma presents as a slowly growing subungual nodule that eventually ulcerates (Fig. 87-20) or a warty periungual growth. The underlying bone is commonly involved. Oncogenic human papillomavirus may be isolated in the lesion. Surgical excision with Mohs surgery is the best treatment for squamous cell carcinoma without bone involvement.

MELANOMA[62–64] (See Chap. 124) Nail melanoma most commonly affects the thumb or great toe and is usually an acral lentiginous melanoma. Most patients are middle-aged or elderly and dark skinned (one-third of nail melanoma occurs in African Americans, Asians, and Native Americans). Longitudinal melanonychia is the most common sign. The band is usually dark and has an irregular border. Periungual pigmentation (Hutchinson nail sign) indicates superficial spreading of the tumor. Amelanotic melanoma is often misdiagnosed as a pyogenic granuloma because it appears as a nail bed growth that first detaches the nail plate and then destroys the epithelium with erosion and bleeding (Fig. 87-21). The low survival rate of patients with nail melanoma is related mainly to the delay in diagnosis.

Although dermoscopy is helpful in evaluating nail pigmentation, because it distinguishes pigmentation due to hematoma from melanocytic pigmentation, dermoscopic criteria for distinguishing melanonychia due to melanocyte activation or nail matrix nevi are still not well defined and reliable. A pathologic study is recommended in all cases of longitudinal melanonychia showing suspicious features (Table 87-10).

▲ **FIGURE 87-19** Nail matrix nevus: melanonychia and periungual pigmentation.

▲ **FIGURE 87-20** Subungual squamous cell carcinoma: ulcerated nodule.

▲ **FIGURE 87-21** Amelanotic melanoma of the nail bed.

MELANOMA AT A GLANCE

- Involvement of nails is rare (0.7 percent to 3.5 percent of melanomas).
- Thumb or hallux is most often affected.
- Longitudinal melanonychia and Hutchinson sign are classic.
- Lesion is amelanotic in 25 percent of cases.
- Only 15 percent of patients survive 5 years or longer.

NAIL PSORIASIS[66] (See Chap. 18)

Psoriasis can be limited to the nails and produce nail signs that mimic those of a large number of other nail disorders. Pitting is considered by dermatologists to be the typical symptom of psoriasis. Psoriatic pits are limited to the fingernails, are large, deep, and irregular (see Fig. 87-4), and represent psoriatic involvement of the proximal nail matrix.

Onycholysis, salmon patches, and subungual hyperkeratosis are additional clinical signs of nail bed psoriasis. Onycholysis is actually the most common manifestation of nail psoriasis and may affect both fingernails and toenails. In fingernails the presence of an erythematous border along the onycholytic area is diagnostic for nail psoriasis (Fig. 87-22). In toenails onycholysis is usually combined with subungual hyperkeratosis and may closely resemble onychomycosis.

TABLE 87-10
Clinical Signs That Require Histologic Evaluation of Longitudinal Melanonychia

- Periungual pigmentation
- Adult age
- Change in color/width of the band
- Hyperpigmented lines within the band
- Proximal portion of the band wider than distal
- Thumb, index finger, or toe involvement
- Blurred margins
- History of trauma (negative prognostic factor)[65]

NAIL PSORIASIS AT A GLANCE

- Present in up to 50 percent of patients with skin psoriasis and up to 83 percent of those with psoriatic arthritis.
- Isolated nail psoriasis is not rare.
- Nail matrix and nail bed are most commonly affected.
- Most often precipitated or worsened by trauma.
- Most common signs are onycholysis, salmon patches, subungual hyperkeratosis, and irregular pitting.
- Fingernails and/or toenails may be affected. Several nails are involved in most cases.
- Treatment is often unsatisfactory.

Salmon patches (oil drop sign) are also diagnostic for nail psoriasis.[67] They are seen in fingernails and appear as yellow-red areas of discoloration in the center of the nail or bordering an onycholytic area (Fig. 87-23). Rarely, nail psoriasis may produce severe nail plate abnormalities such as trachyonychia or crumbling. Other common but rather aspecific signs include splinter hemorrhages and paronychia.

Differential Diagnosis

The differential diagnosis of nail psoriasis is summarized in Box 87-1.

▲ **FIGURE 87-22** Nail psoriasis: onycholysis surrounded by an erythematous border.

▲ **FIGURE 87-23** Nail psoriasis: salmon patches of the nail bed.

Treatment

Treatment of psoriasis affecting only the nails is often unsatisfactory and should be limited to patients who experience functional impairment or severe cosmetic problems. It is important to instruct patients to avoid trauma and to refer the patient to a rheumatologist if digital pain is described.

Systemic treatments for skin and joint psoriasis are generally effective for nail psoriasis (methotrexate, cyclosporin A, biologics). Phototherapy is not effective.

Intralesional steroids (triamcinolone acetonide 2.5 to 5.0 mg/mL in saline) are the best treatment for nail matrix psoriasis limited to a few fingernails, for which they can be injected in the proximal nail fold every 4 to 8 weeks. Acitretin at low dosages (0.3 mg/kg/day) for 4 to 6 months may also be an effective option in severe nail psoriasis. In nail bed psoriasis, topical treatment with calcipotriol or tazarotene reduces subungual hyperkeratosis.[68,69]

Box 87-1

Differential Diagnosis of Nail Psoriasis

- Onycholysis
- Onychomycosis (usually associated with subungual hyperkeratosis): up to 21% of psoriatic nails have secondary onychomycosis
- Idiopathic onycholysis (fingernails): usually seen with other nail changes
- Trauma (toenails): psoriasis usually affects several nails, not just halluces
- Pitting
- Eczema: often has periungual scaling and Beau's lines
- Alopecia areata: different morphology of pits

▲ **FIGURE 87-24** Hallopeau acrodermatitis continua.

PUSTULAR PSORIASIS (See Chaps. 18 and 21)

The diagnosis of Hallopeau acrodermatitis is suggested by a clinical history of relapsing periungual and subungual pustules with onycholysis. The patient is most commonly seen when the acute episode has subsided; at this time the affected digit shows onycholysis with nail bed and periungual erythema and scaling (Fig. 87-24). Low-dose acitretin (0.3 mg/kg/day) may be useful.

LICHEN PLANUS[66] (See Chap. 26)

Nail lichen planus is serious, because it may destroy the nails. It is therefore important to diagnose and treat the disease as soon as possible. Although lichen planus often affects both the nail matrix and the nail bed, clinical suspicion should be aroused by nail matrix signs, particularly nail thinning with longitudinal ridging and fissuring. Dorsal nail pterygium formation is not common (Fig. 87-25). It results from nail matrix destruction and appears as a :-shaped extension of the skin of the proximal nail fold that adheres to the nail bed. Idiopathic atrophy of the nails is a rare variety of nail matrix lichen planus characterized by acute and progressive nail destruction leading to diffuse nail atrophy with and without pterygium. Onycholysis is quite frequent in both fingernails and toenails. Severe toenail involvement causes features that resemble yellow nail syndrome, with thickened, yellow-brown toenails.

Differential Diagnosis (Box 87-2)

In patients with brittle nails, the nail abnormalities are milder. The nails are thin and ridged, but fissuring at multiple sites

▲ **FIGURE 87-25** Nail lichen planus: dorsal nail pterygium.

is not observed. Onychoschizia is frequently associated. Trauma that produces damage to the matrix in an area wider than 3 mm causes permanent thinning and fissuring. Only one nail is usually affected, and it may show a single fissure.

NAIL LICHEN PLANUS AT A GLANCE

- Nail lichen planus is seen in approximately 10 percent of patients with skin lichen planus.
- Nail involvement is not associated with oral, skin, or scalp lesions in most cases.
- Nail matrix lichen planus produces nail thinning, with longitudinal fissuring, dorsal pterygium, and trachyonychia. Nail bed lichen planus is frequent, especially in toenails, but clinical signs are not specific.
- Several nails are involved in most cases. Scarring of the nail matrix with nail atrophy is a possible sequela.
- Diagnosis should be confirmed by nail biopsy, and systemic treatment is necessary to avoid scarring.

Box 87-2

Differential Diagnosis of Lichen Planus

LONGITUDINAL FISSURING

- Brittle nails
- Trauma (single fissure)
- Systemic amyloidosis
- Lichen striatus
- Graft-versus-host disease

PTERYGIUM

- Trauma
- Bullous diseases
- Digital ischemia
- Dyskeratosis congenita
- Graft-versus-host disease

Nail abnormalities may be the first sign of systemic amyloidosis, with nail thinning, ridging, and fissuring closely resembling mild nail matrix lichen planus. In amyloidosis, nail bed hemorrhages are common. Diagnosis depends on nail biopsy. Lichen striatus may manifest as nail thinning and fissuring limited to one or two adjacent digits. Skin changes that course from the affected nail in a linear configuration are typical. Inherited (epidermolysis bullosa) and acquired (e.g., bullous pemphigoid) bullous diseases can produce pterygium. Skin and mucosal lesions are usually present. Digital ischemia is distinguished in that the digit is cold and shows skin signs of impaired vascular skin supply.

Treatment

Nail matrix lichen planus requires oral or intramuscular treatment with systemic steroids, which induce remission of the disease in most cases. Intralesional (vs. systemic) corticosteroid injections should be considered in patients with involvement of fewer than three digits. Dorsal pterygium is not reversible and when the sole manifestation, should not be treated. Solitary nail lichen planus presenting as trachyonychia does not lead to nail scarring and therefore does not necessarily require treatment.

PARAKERATOSIS PUSTULOSA

Parakeratosis pustulosa is a rather common condition that occurs only in children. The disease is limited to one nail in most cases (usually the thumb or index finger) with a clinical picture that closely resembles that of psoriasis (Fig. 87-26). Characteristics are distal onycholysis, fingertip desquamation, and mild subungual hyperkeratosis. Spontaneous regression usually occurs after puberty.

▲ **FIGURE 87-26** Parakeratosis pustulosa: psoriasiform nail changes limited to one digit in a child.

TRACHYONYCHIA (TWENTY-NAIL DYSTROPHY)

Trachyonychia (twenty-nail dystrophy) is a nail sign that can be caused by several inflammatory disorders that produce a mild disturbance of nail matrix keratinization. These include alopecia areata, psoriasis, lichen planus, and eczema. The nail is rough and opaque due to excessive longitudinal ridging. The disease occurs most commonly in children. Trachyonychia does not produce nail scarring, even in cases due to lichen planus.

TRACHYONYCHIA (TWENTY-NAIL DYSTROPHY) AT A GLANCE

- Idiopathic but likely reflects alopecia areata, psoriasis, dermatitis, or lichen planus of the nail. More common in children.
- Characterized by nail roughness due to excessive longitudinal ridging (sandpaper nails).
- Several nails are involved in most cases; involvement of 20 nails is not necessary for diagnosis.
- Nail changes often regress spontaneously.
- Treatment is not required.

▲ **FIGURE 87-27** Nails in Darier disease.

DARIER DISEASE[1] (See Chap. 49)

The nail abnormalities noted in Darier disease are diagnostic but are not seen in all patients (Fig. 87-27). Key features are longitudinal erythronychia, longitudinal leukonychia associated with distal nail plate nicking (: shaped), and subungual hyperkeratotic papules.

ALOPECIA AREATA (See Chap. 86)

Nail involvement is seen in approximately 20 percent of adults and 50 percent of children with alopecia areata and is most common in male patients with severe involvement. Geometric pitting is most typical (Fig. 87-28). Pits are small, superficial, and regularly distributed in a geometric pattern along longitudinal and transverse lines. Trachyonychia is quite common in children affected by alopecia totalis or universalis. Nail abnormalities may improve with systemic steroid treatment or spontaneously; they respond poorly to application of topical medications.

▲ **FIGURE 87-28** Alopecia areata: geometric pitting.

ATOPIC DERMATITIS (See Chap. 14)

Nail abnormalities associated with atopic dermatitis are non-specific in most cases. Manifestations are most commonly Beau's lines, irregular pitting, and chronic paronychia. The condition is often mistaken for candidal onychomycosis. Onycholysis and subungual hyperkeratosis are seen in severe cases, especially those triggered by occupational exposure.

YELLOW NAIL SYNDROME

Yellow nail syndrome may or may not be associated with a systemic disorder and is occasionally familial.[70,71] However, it is important to refer patients to a pneumologist to exclude respiratory tract involvement. Other conditions that may be associated with yellow nail syndrome include rheumatoid arthritis and internal malignancies. The history is the most important clue to diagnosis, because patients always claim that their nails have stopped growing.

The nail changes may benefit from treatment with high oral dosages of vitamin E. Spontaneous improvement is possible. Topical vitamin E and systemic antifungal medications (itraconazole, fluconazole) do not appear to be effective.[70–72]

YELLOW NAIL SYNDROME AT A GLANCE

- In the typical syndrome, nail changes are associated with respiratory disorders and lymphedema.
- Arrested nail growth is diagnostic.
- Nails are overcurved and thickened, the cuticle is absent, and nail color varies from pale yellow to green. Onycholysis is often associated.
- Most or all nails are usually involved.

NAIL SIGNS OF SYSTEMIC DISEASES (Table 87-11)

In systemic diseases, nail manifestations usually involve most or all nails. The diagnosis is suggested by clinical history, morphology, and distribution of the nail abnormalities.

Beau's lines located at the same level in all digits or onychomadesis occurring simultaneously in all digits is strongly diagnostic for nail matrix damage from a systemic cause. Examination and capillaroscopy of the proximal nail fold are very important for the diagnosis of connective tissue diseases (Fig. 87-29). Patients with scleroderma and dermatomyositis show enlarged capillary loops with reduced capillary density and avascular areas (see Fig. 87-29). In systemic lupus erythematous periungual erythema and telangiectasia are typical; although periungual vessels can be tortuous, the capillary density tends to be normal. Cuticular hyperkeratosis and hemorrhages are seen in systemic lupus erythematous and dermatomyositis. Pterygium inversus unguium is typical of scleroderma; in this condition the nail plate adheres to the fingertip skin, which makes nail trimming very painful. The diagnosis of systemic amyloidosis can be suggested by nail involvement, which sometimes precedes skin and mucosal changes. The nails are thinned, longitudinally fissured, and show subungual hemorrhages. Mild leukonychia is often seen in normal individuals and therefore does not represent a specific sign of systemic disorders. Clinical patterns include half-and-half nails (leukonychia affects the proximal half of the nail bed), Terry's nails (leukonychia affects the entire nail bed except for its 2-mm distal margin), and Muehrcke's lines (narrow paired transverse bands parallel to the lunula) (Fig. 87-30). Clubbing may or not be associated with cyanosis (Table 87-12). In clubbing the angle between the proximal nail fold and nail plate is greater

TABLE 87-11
Nail Signs of Systemic Disease

Beau's lines/onychomadesis	See Table 87-2
Koilonychia	Sideropenic anemia
Proximal splinter hemorrhages	Bacterial endocarditis Trichinosis Anti-phospholipid syndrome Altitude sickness
Periungual erythema	Collagen disorders Infection with human immunodeficiency virus or hepatitis C virus
Lichenoid nail changes with hemorrhages	Systemic amyloidosis
Apparent leukonychia	
Half-and-half nails	Renal disorders
Terry's nails	Hepatic disorders
Banded nails (Muehrcke's lines)	Systemic chemotherapy Hypoalbuminemia
Clubbing	See Table 87-12
Melanonychia	See Tables 87-3, 87-10

TABLE 87-12
Causes of Clubbing

  - Bacillary dysentery
  - Amoebic dysentery
- Chronic methemoglobinemia

[a]Unilateral.
[b]Associated with cyanosis.
[c]Associated with hypertrophic osteopathy.

than 180 degrees (Fig. 87-31). The digit has a bulbous appearance, and the nail plate is enlarged and excessively curved. Melanonychia can be associated with a variety of systemic disorders and conditions, particularly human immunodeficiency virus infection, adrenal disease, pregnancy, and certain drugs (Fig. 87-32 and Table 87-13).

DRUG-INDUCED NAIL ABNORMALITIES[73]

A few nail abnormalities are highly likely to have resulted from administration of medication (see Table 87-13). Pyogenic granulomas involving several nails are an occasional side effect of treatment with retinoids, indinavir (Fig. 87-33), and anti–epidermal growth factor receptor chemotherapeutic agents, often leading to drug discontinuation. Retinoids have also been associated with nail fragility and paronychia. Taxanes (docetaxel and paclitaxel) frequently induce painful onycholysis with subungual hemorrhage and abscess formation. The nail lesions resemble a subungual infection and are reversible after drug discontinuation. Both β blockers and bleomycin may lead to digital ischemia. Therapy with psoralen plus ultraviolet A light has been associated with photo-onycholysis and with melanonychia. Photo-onycholysis is a rare phototoxic condition observed after intake of tetracycline derivatives, psoralens, and fluoroquinolones and subsequent exposure to sunlight or ultraviolet A light. It may be associated with a photosensitivity reaction in the skin and typically affects the central part of the nail plate of one or more fingernails. Onycholysis is painful and often hemorrhagic. Thumbnails are often spared.[74]

▲ **FIGURE 87-29** Proximal nail fold capillaroscopy in dermatomyositis: avascular areas and enlarged capillary loops.

▲ **FIGURE 87-30** Muehrcke's lines.

TRAUMATIC NAIL DISORDERS

Nail Biting

Nail biting is common in children and may encourage spreading of subungual warts.

When nail biting is associated with picking and chewing of the cuticle and periungual skin, the nail plate often shows superficial abnormalities and melanonychia due to melanocyte activation.

Habit Tic Deformity (Onychodystrophia Mediana Canaliformis)

In habit tic deformity the thumb shows a central longitudinal furrow with multiple transverse parallel lines (Fig. 87-34). The nail deformity is due to the nervous tic of pushing back the cuticle and the proximal nail fold of the thumb with the index finger.

▲ **FIGURE 87-31** Clubbing.

▲ **FIGURE 87-32** Longitudinal melanonychia involving several nails in a patient undergoing polychemotherapy.

Subungual Hematoma

Subungual hematoma may be caused by a single acute trauma or by repeated microtraumas (see Chap. 98). Nail hematomas last several months because part of the blood is incorporated into the nail plate. Very dark lesions require differentiation from melanic pigmentation. Dermoscopy shows rounded red-black globules.[63,64] Acute hematomas require immediate drainage to avoid matrix compression.

Onycholysis

Traumatic onycholysis of the great toenails is frequent in athletes, in women wearing high-heeled shoes, and in individuals with podiatric abnormalities. Nail detachment is not associated with nail bed hyperkeratosis.

TABLE 87-13

  - Paronychia

▲ **FIGURE 87-33** Multiple pyogenic granulomas in a patient treated with indinavir.

Onychogryphosis

Onychogryphosis is common in the elderly and neglected individuals (Fig. 87-35). The nail is thickened, distorted, opaque, and yellow-brown, and tends to have an oyster shell appearance.

Pincer Nails

Pincer nails is a painful abnormality that usually affects the toenails and may be associated with subungual exostosis. The distal nail plate is overcurved and compresses the subungual soft tissues.

Ingrowing Toenails

Ingrowing toenails most commonly affect young adults with congenital malalignment of the great toenails. Improper nail cutting may lead to embedding of a nail edge, causing inflammation and granulation tissue formation. Hyperhidrosis is frequently associated. The aim of treatment for ingrowing toenails is to extract the nail edge that is ingrowing and prevent further penetration of nail fragments into the lateral folds. To accomplish this, the lateral nail plate can be lifted by using a cotton pack or by inserting a gutter splint along the lateral nail margin.[75] The width of the nail plate can also be reduced by surgical or chemical (phenolization) removal of the lateral nail matrix.[76]

▲ **FIGURE 87-34** Longitudinal furrow of the nail plate due to habit tic.

▲ **FIGURE 87-35** Onychogryphosis. The nail plate is greatly thickened, distorted, and hard.
